National Quarantine the Only Means to a Satisfactory End.—Some years ago we advocated in the pages of the *JOURNAL* time and again the prime necessity of active and satisfactory measures being taken by the National Government to secure adequate protection from the invasion of preventible epidemic diseases, urging the need of a National Department of Public Health, properly organized and equipped as being fully justified by the experiences of the past. The matter, however, was relegated to the Marine-Hospital Service, and we quietly rested on our oars, and have waited patiently to see just what we expected, viz: a failure in a very important and vital field, once! yes, twice and three times! With the culmination and decline of the last visitation, we thought the time opportune to again take up our former line of argument, sincerely hoping that our national law-makers would give this subject the consideration it demanded. The last epidemic and the two preceding ones were reasonably slight as compared with former visitations, but even they caused sufficient loss of life and property interests to have justified far more effective measures of precaution. It has been demonstrated that both cholera and yellow fever can be kept out of the United States—if so, somebody is certainly to blame. The Marine-Hospital Service having proven ineffectual, our national law-makers must shoulder the responsibility if they do not provide something better. With both branches of Congress and the Executive head of the government in the hands of one party—and that party one that has ever shown strong leanings to centralism and paternalism, is it not to be hoped that strong and effective measures on the part of the National Government shall at once be set on foot and the means of relief given in accordance with the demands of the times. The ineffectual efforts of the Marine-Hospital Service, the discordant and irregular methods of State, municipal and local authorities should no longer be tolerated. From one end of the land to the other the people have spoken time and again. Will our law-makers heed their voice and outcry of unison, or will they longer dilly-dally with a question far more important than tariff-tinkering, the currency or acquisition of adjacent islands in either the Atlantic or Pacific. The report from Edwards, Miss., by Associated Press dispatches of January 26, that the yellow fever in that locality has not disappeared gives serious apprehension that the disease may survive the winter and appear again in epidemic form with the coming of warm weather. There has been practically no winter along the gulf coast, and as January is nearly spent, it is probable that there will be no weather sufficiently severe to destroy the germs. If yellow fever ap-

pears again on the gulf coast its spread over the entire South can be prevented only with great difficulty, and as much to be dreaded as the disease itself is the faulty and hysterical quarantine that impedes commerce, prevents travel, produces business stagnation and causes many hardships and inconveniences without effectively checking the spread of the disease. The experience of last year gave proof not only of the insufficiency, but of the positive harmfulness of State and local quarantines. Intelligent co-operation between these bodies seems impossible. They are lacking in means, financial and otherwise, to properly grapple with the necessities of the situation, and having no general direction or concert of purpose their efforts are worse than futile. Quarantine is essentially an interstate matter. It must necessarily in some degree effect the regulation of interstate commerce. To be effective there must be general direction and uniform conduct, and that can be given by the National Government only. The continuance of yellow fever in the gulf coast, therefore, with the strong probability that it will again become epidemic in extreme Southern localities with the coming of warm weather, demands the speedy passage of adequate and effective means by Congress. A bill should be passed in time for the Government machinery necessary for an effective quarantine to be organized and put into operation before the beginning of summer. Nashville has no fear of a visitation of yellow fever. The immunity of the table-lands of Middle Tennessee from the spread of the disease has been thoroughly demonstrated, but Nashville has a very near interest in the proper regulation of the quarantine. The trade of the city suffered greatly last fall because of the prevalence of shotgun quarantine throughout the region to the south of us, wherein the representatives of Nashville houses constantly travel. The State of Tennessee has a very strong interest in the establishment of proper quarantine laws, because all of the western portion of the State is subject to the ravages of the disease. The Gulf States are vitally interested in this question, and to every State in the Union by both sympathy and interest, it is a question of paramount importance that should be met in only a practical manner, regardless of old-time traditions of State rights, or party slogan, or a partisan feeling. It is a question that demands the highest order of statesmanship regardless of party success or present or future personal welfare of those to whose solution it is entrusted.—Editorial, *Southern Practitioner*, February.

NECROLOGY.

S. G. MATSON, M.D., Viola, Iowa, born in Vermont, March 5, 1808, died in Fayette, Iowa, February 5. His early life was spent in New England, and he was graduated from the Medical Department of the University of Vermont in 1832. In 1845 he removed to Iowa. In 1846 he was a member of the Constitutional Convention which formed the first constitution of the State of Iowa. He was also elected a member of the first general assembly of the State, which met at Iowa City, Nov. 30, 1846, and in extra session, Jan. 3, 1848. Failing by one vote of being elected speaker of the house, he became chairman of the committee on schools and took a leading part in enacting the first school laws of the State. He also prepared and introduced the bill locating the State University at Iowa City, and was afterward a member of its first board of trustees. In politics he was originally a "Jefferson democrat," but united with the republican party at its organization and voted for John C. Fremont for president in 1856. He continued an ardent republican, casting his last presidential vote for Wm. McKinley in 1896. In appreciation of his services rendered the State, by request, a life-size oil painting of Dr. Matson was secured and placed in the Historical Department of the Capitol, at Des Moines.

JOHN CRONYN, M.D., Buffalo, N. Y., died February 11, aged 73 years. Born in Ireland, he located in Toronto, Can., in 1837, and later entered the University of Toronto. In 1850 he passed his medical examinations but did not take the degree owing to the test of oath which required graduates to subscribe to the thirty-nine articles. Being a Roman Catholic he refused to do this and was obliged to go before the Provincial Licensing Board, which admitted him to practice. A few

years later the Canadian Government removed all sectarian restrictions and he obtained his degree of M.D. His thesis received the Chancellor's prize. In 1859 he moved to Buffalo. In 1883 he was largely instrumental in the establishment of the Medical Department in Niagara University. He was soon appointed to the chair of professor of principles and practice of medicine, and later made president of the college faculty. He held this position until his death. In 1888 Niagara University conferred on him the degree of Ph.D. and in 1893 that of LL.D. For several years Dr. Cronyn was a member of the board of directors of the Buffalo State Hospital, and was once president of the board. During the last twenty years he has been president of the New York State Medical Society and at different times president of the Erie County Medical Society. He was an honorary member of the Ontario Medical Association.

JOHN G. TRUAX, M.D., Rush Medical College, Chicago, 1871, died at his home in New York City February 16. He was born in Durhamville, N. Y., March 5, 1848, and for two years after graduation served in the Chicago hospitals, and then went to the Peninsula on Lake Superior, where he remained among the iron mines until 1876, when he went to New York, eventually to fill many responsible positions in social and club life. A recognized authority in pottery, he was also the possessor of the works of many foreign and American artists, wrote considerably for the New York State Medical Association, and participated somewhat in the debates of the New York County Medical Association, before which he first introduced his alcoholic test for urine. His predilections, however, were for hospital work and dealings with large bodies of the community; hence he was a pension examining surgeon, a visiting physician to the Harlem Hospital, a member of the Board of Governors of the New York Juvenile Asylum and chairman of the Board of Trustees of the Mott Memorial Library.

ARNOLD STUB, M.D., Geneva Med. Coll. N. Y., 1872, died in Brooklyn, N. Y., during the second week in February. Born in Ebling, Prussia, in 1832, he came to this country when 24 years old. He entered the volunteer army during the civil war, served as medical purveyor under General Hancock, and was mustered out as surgeon of the 90th N. Y. Vol. Inf. on Jan 3, 1865, after which date he became a resident of Brooklyn.

CHARLES J. BICKHAM, M.D., Tulane University Medical Department, New Orleans, 1856, died at his home in New Orleans on February 14, aged 69 years. He filled many offices of trust in the line of his profession, and was prominent in the late yellow fever epidemic as an expert authority.

DR. SELWYN CLARK, M.D., Rockford, Ill., died February 12, aged 59 years. He was a graduate of Beloit and the College of Physicians and Surgeons, New York, 1865. He served as a surgeon in the 25th regiment, Illinois infantry. His health was shattered during two months' imprisonment in Libby prison. For many years he was a trustee of Rockford Seminary.

WILLIAM T. ELMORE, M.D., Dartmouth, 1888, died from pneumonia in New York City, February 12, aged 44 years. His birthplace was Montgomery, Ala. He went to New York fifteen years ago.

SUMNER LAUGHTON, M.D., Bangor, Maine, died February 8, aged 86 years. He was a graduate in medicine from Bowdoin in 1834; was later president of the State Medical Society, an honorary fellow of the Maine Academy of Medicine and a member of the AMERICAN MEDICAL ASSOCIATION. At the time of his death he was chairman of the Maine Board of Registration.

STEPHEN W. VAN DUYN, M.D., New York University Medical College, 1865, died in Plainfield, N. J., January 25, aged 61 years. He was a war veteran, having been mustered out of the United States service April 13, 1865, as assistant surgeon of the First Regiment New Jersey Cavalry. From 1866 to 1869 he was an assistant surgeon U. S. A., and subsequently was many years in practice in Newark, N. J.

MISCELLANY.

An Anonymous Benefactor.—A benevolent Hamburger, who withholds his name, has bequeathed 250,000 marks for the erection of a hospital with rooms for one hundred tuberculous patients, who are to get bedding, board and treatment for twenty-five cents per day.

Editorship of the "British Medical Journal."—The vacancy in the editorial chair made by the death of Mr. Ernest Hart, has been filled by the promotion of Dr. Dawson Williams, the assistant editor, to the editorship. Mr. C. Louis Taylor, the sub-editor, succeeds Dr. Williams as assistant editor.

Purulent Peritonitis.—By this name Franke describes a generalized suppuration spreading extraperitoneally, between the peritoneum and fasciæ, all around the abdomen, and reports two cases, one of which recovered and a necropsy was impossible in the other. An abstract in the *Cbl. f. Chir.* rather doubts the correctness of the diagnosis.—*Mittb. d. Grenzgeb. der Med. u. Chir.*, Vol. 2, Nos. 1-2.

Tribenzoylgalllic Acid. A preparation under this name has been brought out, which is said to be prepared by agitating an alkaline solution of gallic acid with benzoyl chloride and purifying the resulting product by recrystallization after exhausting with boiling water. The compound appears to remain unchanged by the secretions of the mouth, esophagus and stomach, but in the intestines is readily split up, gallic acid being reformed and exerting its specific properties.—*Druggists' Circular*.

Antivivisection in Germany.—Some years ago an antivivisection movement was started in Germany, and the government asked Virchow's opinion on the matter. He took the current textbook on physiology and marked with a blue pencil all the paragraphs in which it stated that the fact had been established by experimentation on animals, and sent the heavily marked book without a word of comment as his reply. The subject was dropped at once, and probably forever in that country.

Encysted Calculus.—Professor Guyon stated, in 1894, that he had never encountered an encysted calculus and doubted their existence, but Ortiz of Buenos Ayres, reports four cases in which he discovered an additional calculus encysted in the wall of the bladder, and observes that probably many others have been overlooked by surgeons in operating. It is difficult to differentiate such a calculus; the only guide is a lack of mobility, and palpitation during lithotomy.—*Anales del Circ. Méd. Argentino*, November.

Chinopyrin.—Chinopyrin is the name suggested by Santesson for a combination which is made by mixing three parts of quinin hydrochlorate, two parts of antipyrin and six parts of water, the mixture being then warmed. The disagreeable effects of quinin are mitigated by this form of exhibition; it is particularly suitable for subcutaneous injection in cases where administration per os was inadvisable. Its antipyretic powers, grain for grain, are somewhat less than those of quinin. The name quinopyrin has also been suggested for this combination.—*Deutsche Medicinische Wochenschrift*.

A Vitiated Policy.—In an action brought by a policy-holder for the recovery of \$10,000 from a life-insurance company the justice of a New York court very rightly decided in favor of the defendant. The points of the case were that in the application dated November 15, 1895 the warrant was given that the health at that time was good and also that no physician had been consulted since the previous January. The further agreement was that the policy should take effect only in case of good health at the time of its delivery, which was Dec. 4, 1895. The evidence showed that physicians had been consulted within the limit restricted, that the diseases which caused death were of acknowledged gravity and that the policy was received on the death-bed. The party who held the policy died Dec. 4, 1895.

Section Work in the British Medical Association.—The differentiation of work in the British Association goes on. The number of sections that are to be provided for at the Edinburgh meeting next July will be sixteen. The subjects of anatomy and physiology have been assigned to separate sections; three other subjects, "Neurology," "Medicine in Relation to Life Assurance" and "Tropical Diseases," have grown to the stature that seems to demand separate sectional development. Our own great Association is at present able to get along with a fewer number of compartments, namely, twelve, in the hull of our own craft. What the next specialization will be by the British Medical Association is not easy to foresee.

Dr. Weir Mitchell's Novel.—The *Bookman* states that Dr. Mitchell's recent book "Hugh Wynne," is one of the most popular of those now on the current list. An amazing incident in connection with the book is a critique thereof that has appeared in *The Friends' Intelligencer*, a kind of organ of the Quakerdom of Philadelphia, and that has been separately printed in pamphlet form. While doing full justice to the literary merits of the book, the Quaker reviewer shows up a number of historic mistakes into which the author has fallen in regard to the Quakers of the Revolutionary period, their customs and discipline, together with misapprehensions as to the personal characters of several of the historic characters of the novel. The reviewer regards the novel as an unfavorable picture of the Friends of that period, and in a very gentle but none the less effective manner, exposes what he considers the Doctor's mistakes. If you happen to come across the review be sure to insert it in the copy of your novel, for it is worth preserving.

Reaction Time in Abnormal Conditions of the Nervous System.—Recent investigations in the Yale psychologic laboratory, made in cases of neuritis, locomotor ataxia, alcoholism and hysteria, are recorded in the *Medical Record* of February 5. The results go to show that: 1. Alcoholism shortens the simple reaction time, hysteria leaves it unchanged, and local neuritis, multiple neuritis and locomotor ataxia lengthen it. 2. Local neuritis scarcely lengthens the additional mental processes involved in complex reaction time; alcoholism lengthens them somewhat, while locomotor ataxia, multiple neuritis and hysteria double and triple the normal time. 3. The individual's regularity is much greater than normal in locomotor ataxia and alcoholism, and much less than the normal in the other diseases. The irregularity is specially marked in hysteria for the higher mental processes. 4. Subjects with multiple neuritis, locomotor ataxia and alcoholism are much more distinctly marked off in respect to the tests than normal individuals.

Insurance of Students in Germany Against Laboratory Accidents.—Since the beginning of the academic half-year all students attending the chemic and physical laboratories of the University of Heidelberg have been insured against accidents happening in the course of the lectures, of the laboratory work and of scientific excursions. The insurance premium is paid by the treasury of the University, which has also made a new regulation in connection with the subject requiring the students to pay a small sum in addition to the class fees. This step is surely deserving of imitation by other universities and such advantages ought not to be limited to laboratory work only, for medical students run much greater risk both in the dissecting rooms and as dressers in the surgical clinics, and as clerks in the infection wards of the university hospitals. This fact should be considered by the other universities in the event of their imitating the example of Heidelberg.

Selling Medicine for Trick Purposes on Assault and Battery.—A conviction of assault and battery, in the case of State vs. Monroe, of most peculiar character, was affirmed by the supreme court of North Carolina, Dec. 21, 1897. An individual, Will Horn, had administered to one Ernest Barrett a dose of croton

l, and the oil had had an injurious effect on Barrett. This led to the prosecution of the defendant Monroe for assault and battery. Monroe admitted that he sold the oil to Horn, and at his request dropped it into a piece of candy, but denied that he knew that these parties were playing practical jokes on each other, and denied knowing for what purpose Horn wanted the oil. His guilt as a principal, not as an accessory, the court holds, depended upon whether he knew, or had reason to believe, that the dose was intended for Barrett or some other person as a trick, and not for medicinal purposes. Upon the whole evidence, he was found guilty. The instruction given the jury that if the defendant knew or had every reason to believe, and did believe, when he sold the oil, that it was intended for Barrett or some other person as a trick or joke, and not for a medicinal purpose, the defendant would be guilty of assault and battery; also that it was not necessary that it should be a poisonous or deadly dose; but that it was sufficient if it was an unusual dose, likely to produce serious injury, the supreme court pronounces unobjectionable, in point of law.

"Governor" Lutz.—Missouri has a governor who has apparently made it a point to antagonize the medical profession at every point, and some aggressive members of the St. Louis Medical Society have proposed that Dr. F. J. Lutz, the well known physician of St. Louis, shall take the place at the next election: Governor Lutz would honor the place.

The New Anatomy.—In a case reported by one of the New York dailies, "a fracture of the 'hypoid ball' in the victims' throat" is reported. It is to be hoped that the Eastern "General Reader" will not be led into his usual bootless search after novelties, notwithstanding the fact that the culprit may have been misguided by De Quincey's brochure, "On Murder Considered as a Fine Art." Chicago, for the present, is obliged to be content with a students' snow-ball fight in which the police were driven off with some few bruises and possibly with what Mark Twain designates as "rows of acrostics."

Hospital Having School Must Pay Duty.—In reply to a letter of inquiry from the superintendent of the Roosevelt Hospital of New York, Assistant Secretary of the Treasury W. B. Howell stated, January, 1898, that there is no provision of law under which scientific instruments, etc., can be imported free of duty for a hospital, although a school of instruction may be connected with such institution. Paragraph 638 of the act of July 24, 1897, provides for the free entry of philosophic and scientific apparatus, etc., when imported in good faith for the use and by order of any society or institution incorporated or established solely for religious, philosophic, educational, scientific or literary purposes, whereas, Mr. Howell declares, a hospital is not established solely for such purposes.

Primary Tuberculosis of the Nose.—The rarity of this affection makes a case reported in the *Laryngoscope* (February) of interest. The growth, slightly larger than a cherry, and irregular, was located on the cartilaginous septum, attached by a broad base, rather firm to the touch and not freely movable. Under cocaine anesthesia the large part of the tumor was removed with a cold wire snare, and the remainder destroyed by the electro-cautery and concentrated solutions of lactic acid (beginning with a 40 per cent. and increasing to an 80 per cent. solution), with iodoform insufflations, were used. The diagnosis was confirmed by the microscope. The patient, after a year and a half, is absolutely well and presents a normal septum.

Serum Diagnosis of Yellow Fever.—In the *New Orleans Medical and Surgical Journal* (February) a series of 100 cases are given by Archinard and Woodson in which the agglutinative test was applied to the bacillus icteroides and controlled by its application to the bacillus typhosus. The authors claim that since their work has been along the lines laid down by Sana-

relli, they have made various departures therefrom, not the least of which has been this application of Widal's method of serum diagnosis to the bacillus icteroides. The first fifty were taken from typical yellow fever cases, the second fifty being suspect blood and including cases of typhoid fever, malaria and yellow fever. The authors' conclusions are: 1. Our work demonstrates the practical value of serum diagnosis in yellow fever. 2. That it may be utilized as early as the second day, and be exceptionally present as late as nineteen years after the disease. 3. That a dilution of 1-40 with a time limit of one hour is to be preferred for accuracy of diagnosis. 4. That the dried blood method of Wyatt Johnston is perfectly satisfactory. 5. That the serum diagnosis of yellow fever should be instituted in all countries wherein the disease may exist endemically, or which may be occasionally visited by epidemics. 6. That it is exceptionally valuable at the beginning of epidemics in the diagnosis of early and doubtful cases.

Trained Nurses at the Health Exposition.—At New York's Health Exposition to be held for five weeks, beginning April 25. The most important single department, both from a popular and educational standpoint, will be the Trained Nurses Educational Exhibit, which will occupy one entire wing of 12,000 square feet on the second floor. The display here will comprise everything in modern hospital and sick room service, an historic collection representing the advance in medicine and surgical science during the century. There will be a sick room not only of the rich house with all expensive appliances in furnishings, but also a duplicate of the sick room in the house of the very poor. The manager of this department is Miss Mary E. Wadley of the Bellevue Post-Graduate School. Exhibits have already been secured from nearly all the hospitals in New York and Brooklyn, and the co-operation of all the nurses in the country is desired. During the first week of the Exposition, there will be a convention of the National Association of Trained Nurses at the Grand Central Palace. An attractive corner of the second floor will be occupied by the Domestic Science Department of the W. C. T. U. in charge of Miss Marion A. McBride of Boston. Here there will be noon-day talks on everything connected with this branch of the W. C. T. U. work, such as "Nutrition," "Cooking without Alcohol in the Home and Hospital", etc., and afternoon receptions and 5 o'clock teas daily.

Does Not Appreciate Some Fine Distinctions as to Expert Evidence.

—It is laid down in the books that a question to an expert witness should not be so framed as to invade the province of the jury. With this for its text the supreme court of Minnesota says, in the case of Donnelly vs. St. Paul City Railway Company, December, 1897, that the line of cleavage between what does and what does not invade the province of the jury is not capable of definite location by any exact rule applicable to all cases without regard to the subject of inquiry. The mere fact that the opinion called for covers the very issue which the jury will have to pass upon is not conclusive that it is not the proper subject of expert or opinion evidence. For example, sanity or insanity is the subject of expert testimony, although that may be the sole issue to be determined by the jury. Continuing, the supreme court says that neither does it appreciate the fine distinctions sometimes sought to be drawn between asking an expert whether in his opinion, certain causes might produce certain results, and asking him whether, in his opinion, they did produce such results. It is well settled that the opinions of medical experts as to the cause of death are admissible, such opinions being founded either upon the personal knowledge of the facts in the case, or upon a statement of the nature of the injury or symptoms and nature of the disease as testified to by others. There can be no difference in principle, the supreme court further asserts, between an opinion as to the cause of death and one as to the cause of physical ailments which

have not resulted in death. So it holds that when the issue is whether the present bodily ailments of a party were caused by certain injuries, a medical expert may give an opinion as to the cause of such bodily ailments, founded upon a statement of the nature of the injury, the subsequent symptoms of the party and *his present physical* condition as testified by others.

Tuberculosis of the Bones and Joints.—In a report of observations on more than one hundred tubercular joints made by Nichols of the Sears Pathologic Laboratory of the Harvard Medical School (*Boston Med. and Surg. Journal*, January 27), the following conclusions are of interest: Injuries of moderate severity favor the production of the disease. In the bones the disease begins in the epiphysis, and is more extensive than appears on gross examination; hence, in operations for removal of the disease a considerable margin of apparently healthy bone must be removed. Tuberculosis of the joints is generally, if not always, secondary to tubercular disease in the epiphysis of an adjacent bone. Abscess formation is due to extension of the tubercular process to the soft parts; the contents and wall of the tubercular abscesses are different from those of infectious abscesses; partial removal of the abscess wall is harmful. Repair is caused by the formation of fibrous tissue, which replaces and partly encapsulates the tubercular tissue; repair may be incomplete; fibrous tissue may produce fibrous ankylosis, or the tissue may become ossified and lead to bony ankylosis. Paraplegia in Pott's disease is rarely due to direct bony pressure; usually the pressure is caused by tubercular peripachymeningitis; rarely the pressure causes degeneration of the cord.

Kocher's Method of Amputation of the Female Breast.—*Annals of Surgery* for February describes this method at length, as reported to the Section on Surgery of the College of Physicians of Philadelphia by George B. Wood, M.D. "The salient points of difference between this operation and the one mostly in vogue in America, that of Halsted, are: 1, the incisions are different; the axillary incision of Kocher's allowing a free entrance to the armpit, and not necessitating the loss of time required in dissecting back the triangular skin-flap of Halsted's operation. By Kocher the axilla is cleaned from above downward and inward toward the chest, while Halsted makes the dissection from within outward and upward. Here it is claimed for the Halsted operation that the removing of fascia in this direction is easier and attended with less hemorrhage. The vessels supplying the axilla begin above and run downward, and it is easier to dissect out a vessel from the base toward the periphery than in the other direction. . . . But where the operation of Kocher saves time as compared with that of Halsted, is in the removal of the pectoral muscles; it being much easier to strip these muscles downward and inward off the chest and then to cut through the origins than it is to dissect off each rib attachment separately, as is required where the pectoral muscles are removed upward and outward. Also, in the Kocher method no extra dissection of the pectoralis minor is required. By beginning as advised by Kocher the annoyance of having a large, loose mass of tumor, fat and muscle to take care of during the dissection of the axilla is avoided. The idea of sawing through the clavicle in case of involvement of the supraclavicular glands belongs to Kocher, and though it may seem to some unnecessary, it certainly gives a much better chance to dissect the lymphatics from around the vessels.

Washington.

REPORT OF THE HEALTH OFFICER.—The report of Health Officer Woodward for the week ended February 12, shows the total number of deaths during the week to have been 106, of which number 48 were white and 58 colored. Among the principal causes of death were: Diseases of the nervous system, 14; urinary, 9; circulatory, 7; respiratory, 26; 3 from la-

grippe, 1 from diphtheria; 3 from whooping cough and 1 from measles.

MICROSCOPIC SOCIETY.—At the recent meeting of the Microscopic Society, Dr. Robert Reyburn read a paper entitled "Bacteria," and gave the life, history and general description of most of the forms with which the pathologist has to deal. The paper was made more interesting by lantern-slide illustrations.

MEDICAL SOCIETY.—At a meeting of the Society held on the 14th inst., Dr. McLaughlin read a very valuable paper, entitled, "The Uric Acid Diathesis in its Relation to Skin Diseases." Dr. Lamb presented the following interesting specimens: pericarditis and pneumonia; ruptured Graafian Follicle from a Cow; teratological specimen.

PHYSICIANS RESIGN.—Four of the most prominent members of the attending staff of the Garfield Memorial Hospital have recently handed in their resignations, thus severing their connection with that institution. The physicians who resigned are: Samuel S. Adams, George N. Acker, James C. McGuire and Joseph H. Bryan. Some time ago, it will be remembered, W. W. Johnston severed his connection with the institution. These gentlemen for some time have disapproved of certain administrative methods of the hospital and recently discovered that some of the lay hospital authorities were clandestinely offering their positions to other physicians in the District. To the credit of the physicians, it may be stated that some declined absolutely to succeed these gentlemen, under the circumstances. There has always been trouble in this institution between the medical men and the laymen on the board, because of the domination of the latter over the physicians, in purely medical questions. It is high time that the profession of the District of Columbia should discipline this institution and demand the respect due the medical men on their board and staff. These gentlemen who have resigned are well known to the profession of this country and an unbiased mind can readily appreciate the loss to the institution resulting from their resignations.

CENTRAL DISPENSARY AND EMERGENCY HOSPITAL.—The report of the Central Dispensary and Emergency Hospital for the past month shows the total number of new cases to be 553; total visits, 1869; emergency cases, 292; house cases, 38; deaths, 6; ambulance calls, 44; prescriptions, 2438.

SANITARY NEEDS OF INSTITUTIONS.—Health Officer Woodward has submitted to Chairman McMillan, of the Senate District Committee, a statement of the sanitary conditions of a number of charitable institutions in the District. Dr. Woodward suggests many changes and improvements and points out many preventable defects which need prompt relief. Chief among these may be mentioned, defective buildings, overcrowding, defective plumbing, deficient bath accommodations, defective light, heating and ventilation and lack of isolating accommodations for contagious diseases.

THE TELEPHONE WAR.—The physicians of the District have joined in the general sentiment against the overcharge, poor service and eaves-dropping methods with respect to messages, which are now in vogue by the local telephone company. A large and enthusiastic meeting was held on the 17th inst., at the Medical Association rooms, which resulted in the passage of resolutions denunciatory of the telephone grievance, and the appointing of a special committee to wait upon the Telephone Company for the purpose of securing better service, unlimited use and secrecy in regard to medical messages passing through their central office. The committee consists of Drs. G. Wythe Cook, H. P. Thompson and H. L. E. Johnson.

WASHINGTON OBSTETRICAL AND GYNECOLOGICAL SOCIETY.—The 276th meeting of the Washington Obstetrical and Gynecological Society was held at the residence of Dr. Kelly, No. 1312 15th st., N. W. Dr. E. A. Ballock presented a very interesting paper on "Adenoma of the Breast," which was fully and freely discussed by the members present.

Detroit.

THE REGULAR MEETING of the Wayne County Medical Society was held February 17. Dr. W. F. Metcalf read an interesting paper on "Office Treatment of Gynecic Cases." The Doctor discussed the subject in a general way, giving the most important conditions and symptoms which are found necessary to treat in regular office practice. Dr. Hal. C. Wyman followed with a paper on "A Wound of the Pericardium and Pleura Treated by Suture: Recovery." The Doctor stated in his paper that some ten days previously he had been called to a town in the interior of the State to treat a man who had been wounded in the chest by the bursting of a saw. He found the man lying on his back with a pulse of 140, respiration 56. On examining the man's chest he found a large gaping wound in its wall through which the heart projected at each respiratory movement. The rent included both the pleura and pericardium. Pushing the apex of the heart back into its normal position, the Doctor grasped the torn edges of the pericardium and sutured with catgut. The pleura was then closed and the chest wall hermetically sealed without drainage. The patient's condition at once improved and he is now convalescent. Dr. W. H. Poole presented the report of a very interesting case of rhinolith, which had by its presence in the middle meatus of the left naris produced symptoms of stenosis of the tear-duct of that side.

AT A RECENT meeting of the Board of Health the resignation of Dr. Samuel Duffield as health officer of the city was accepted, and Dr. Heueage Gibbs of Ann Arbor elected as his successor. This action of the Board has the approval of the majority of the profession in Detroit, as Dr. Gibbs is highly esteemed for his distinguished learning and ability.

Denver.

HOW MAY THE MORTALITY IN APPENDICITIS BE DIMINISHED?

Dr. Charles A. Powers opened the scientific program by the reading of a paper on the above subject, in which he has given the histories of fifteen cases of acute appendicitis seen by him during the past four months. He classified them as follows: 1. Cases which had developed general suppurative peritonitis when first seen, five. 2. Cases of local appendicitis ten. Five cases in the latter class were submitted to operation, all recovered. In the remaining five cases he had advised against operation, and all of these recovered. Of the five cases of general peritonitis operative interference offered absolutely no chance of recovery. Each of these died. Of the complications met during the operation one deserves particular notice. On operation the whole right side of the abdomen was found to be the seat of old, dense adhesions; the appendix lay in the pelvis; it was long, large and gangrenous and densely adherent to all the tissues about it. On digging it out with the finger a gush of straw-colored fluid came; this fluid was urine. He at once packed the wound with gauze and opened the abdomen in the mid-line and examined the bladder, which was intact. After ligature of the appendix the entire wound was freely packed with iodoform gauze, a glass tube being inserted to the pelvis and another at the upper part of the wound behind the colon. Through these channels the urine found ready egress. The fistula closed at about the sixth day, after which the patient went on to complete recovery. Dr. Powers has no sympathy with the extremists who cry loudly for operation in every case. "We must base our decision," he said, "for or against operation on the evidences taken as a whole." Timely operation is safer than delay, and in doubtful cases an exploratory incision will be attended with less danger than will delay. Dr. P. D. Rothwell gave the histories of several cases in which the symptoms indicated appendicitis but the diagnosis of impacted feces was corroborated by emptying the colon. He favors flaxseed poultices, laxatives and purgatives. Dr. Whitney said that 80 per cent. of all cases of appendicitis recover of themselves. He classified appendicitis into cases: 1, which come abruptly and

manifest general infection; 2, localized appendicitis with severe symptoms; 3, mild cases, and 4, cases which begin mildly and rapidly develop alarming symptoms.

Dr. Sewall said he is interested in the prophylaxis of appendicitis which alone could diminish the mortality. The appendix is an organ of low vitality and can not withstand any insults. Impaction is the prime cause.

Dr. Bonney said the majority of cases he had treated were mild. The surgeon he thinks should be called in early. He related a case of a woman 30 years old who presented all the symptoms of appendicitis, and in which the consent for operative interference could not be obtained. On the fifth day convalescence set in. On the tenth day she developed a chill, pain in cardiac region, pericarditis, pleurisy and then pneumonia and lastly nephritis with fatal termination. Probably the appendicitis preceding had much to do with the course of the succeeding phenomena. Dr. Leavitt called attention to the need of an early consultation in cases of appendicitis.

Dr. Hershey said he believed in preventive measures, and believes that in the majority of cases an acute or chronic enteritis can be traced to have been the cause. He thinks that cases requiring surgical interference are very few indeed. Dr. Freeman said his rule is that if within forty-eight hours the symptoms do not tend to increase in severity he treats it expectantly. All cases starting with violence, he operates at once. He does not operate on cases seen on the fourth or fifth day, but waits until the seventh because of the adhesions that are being formed during that period, and which are the barriers nature throws out. If the appendix forms part of the abscess he lets it alone. Patients having suffered from repeated attacks of appendicitis, and who live outside the reach of a surgeon he advises an operation between the attacks. Dr. Rogers referred in his remarks to the great injustice done by the daily papers to the cause of surgery in general and appendicitis in particular. The cases that recover are not reported, but fatal cases receive a write-up, especially if the patient happens to be prominent in the walks of life. He mentioned a certain town where the physicians dare not operate on appendicitis. If they did, it would be at the risk of their lives. Dr. Grant recommended very early operation, and believes that should all operations be performed the first twenty-four hours the statistics would show different figures. Dr. Lobingier also favors early operation; urged the advisability of consultation with surgeons. Reported a case of a woman who was operated on twenty-seven hours after the initial symptoms. Pus was found in abdominal cavity, but the patient recovered. Dr. Nichols took exception to Dr. Freeman's views. Under no circumstances does he leave the appendix in the abdomen. Dr. Wetherill made an analogy between the appendix and Fallopian tubes. The successful cases he thinks are due in a great measure to the skill and dexterity of the operator, and a general surgeon can not expect the results obtained by a Joseph Price or John B. Deaver.

Letters were read from Senators Wolcott and Teller in answers to resolutions passed at its last meeting, protesting against the passage of the bill for further protection of cruelty to animals in the District of Columbia. Both Senators express their willingness to interpose the passage of the bill.

RESOLUTIONS ON VIVISECTION PASSED AT THE STOCK GROWERS' CONVENTION.—At the convention of the national stock growers held recently in this city, the following resolution was unanimously adopted:

WHEREAS, Viewing with alarm that a bill before the present Congress, known as the anti-vivisection bill, purporting to be antagonistic with scientific methods used in placing knowledge in the minds of scientists, for the protection of live stock and prevention of the spread of disease which can alone be acquired by scientific methods; be it

Resolved, That we, the representatives of the live stock interests of the United States, in convention assembled in Denver, Colo., under the call of a national convention of live-stock

men for the purposes of protection of the industries we represent, call upon the Congressmen and Senators of the State here represented to cast their vote against any measure that will prevent scientific research to be continued in the interests of the animal kingdom.

From the further fact that immediate action is about to be taken on the above bill, it is further resolved that the secretary of this convention be requested to convey this resolution to the Congressmen and Senators of the States at interest at once.

MEAT FROZEN FOUR YEARS AGO.—Whether there are such epicureans who will relish viands four years old is a matter for gastronomes to decide. Our health commissioner, without waiting for a decision from the connoisseurs, has seized and destroyed 40,000 pounds of such venerable article. It is said that the killing was done in Omaha, Neb., in 1894, frozen and hung in a refrigerator, and the dealers waited for a favorable opportunity to feed with it some community which does not know of its antecedents.

NEXT MEETING OF THE AMERICAN MEDICAL ASSOCIATION, JUNE 7 TO 10, 1898.—At a recent meeting of the Committee of Arrangements the following has been reported: The medical profession of the city have subscribed the amount of \$6000. The Committee on Meetings reported that the Gulf Railroad has published 20,000 copies of a pamphlet entitled "Colorado, About its Climate." The Committee on Hotels has gotten out an attractive leaflet giving the hotels and principal boarding-houses of the city. The Committee on Souvenir Book reported they have in preparation an exceedingly attractive souvenir volume, profusely illustrated, giving information on every imaginable subject of interest in the State, as well as a map of the State and city. It is confidently expected that the railroads will furnish an excursion "over the loop" and to Colorado Springs and Manitou, and that half rates will be charged for transportation and a time limit on all railroad tickets, of thirty days from the date of arrival.

Hospitals.

ACCORDING to the "Thirteenth Annual Report of the New York Post-Graduate Hospital" from Oct. 1, 1896, to Oct. 1, 1897, 2303 house patients were treated. Of these 823 were babies. In the dispensary 19,017 patients were treated, to which 65,536 visits were made. Of 116 cases investigated as to their being eligible to charity treatment 52 were found deserving, 20 gave fictitious addresses and 44 were turned away. Of the 2303 cases 1326 were treated absolutely without fee, 527 on partial payment and 550 were pay patients.

THE MARYLAND HOSPITAL FOR THE INSANE reports Oct. 31, 1897, during the year the number treated was 610. Forty-three patients died and fifty-three were discharged. The percentage of recoveries of the number treated was 6 per cent. Eliminating those cases of over a year's duration, the recoveries were 80 per cent.

Societies.

The following recent meetings are noted:

Alabama.—Cullman County Medical Society, Cullman, February 7.

California.—Pasadena Medical Society, February 10.

Connecticut.—Hartford Medical Society, February 7.

Illinois.—McDonough County Medical Association, Macomb, February 7.

Indiana.—Johnson County Medical Society, Franklin, February 10.

Iowa.—Southwestern Iowa Medical Society, Creston, February 17.

Massachusetts.—Boston Medical Society, February 14.

Missouri.—Academy of Medicine, Kansas City, February 12; City Hospital Medical Society, St. Louis, February 17; St. Louis Medical Society of Missouri, February 19.

Nebraska.—Lincoln Medical Society, February 8.

New Jersey.—Atlantic Academy of Medicine, February 11.

New York.—Albany County Medical Society, February 16; Binghamton Academy of Medicine, February 15; Jenkins Medical Society of Mount Vernon, February 10; Rensselaer County Medical Society, Troy, February 8.

Ohio.—Delaware County Medical Society, Delaware, Feb-

ruary 15; Jackson County Medical Society, Wellston, February 8; Muskingum County Medical Society, Zanesville, February 10.

Pennsylvania.—Delaware County Medical Society, Chester, February 10; Lackawanna County Medical Society, Scranton, February 10.

Tennessee.—Smith County Medical Society, Carthage, February 7; White County Medical Society, Sparta, February 10.

Texas.—Hunt County Medical Association, Greenville, February 7.

CHANGE OF ADDRESS.

Bovine Co., The, from 495 W. Broadway to 75 W. Houston St., New York, N. Y.

Bennett, Alice, from Wrentham, Mass., to Biltmore, N. C.

Blech, G., from Detroit, Mich., to 6236 Sangamon St., Chicago.

Cockey, M. G., from Topeka, to Belvue, Kan.

Herrick, A. B., from Lisbon, N. D., to Santa Rosa, Cal.

Holmes, C. R., from 84 N. 7th to 8 E. 8th St., Cincinnati, Ohio.

Hill, F. E., from 10 W. 9th to 23 E. 9th St., Cincinnati, Ohio.

Norman, J. B., from Hume to Pilot Grove, Mo.

Olsen, A. B., from Chicago to Battle Creek, Mich.

Pomeroy, H. M., from New York, N. Y., to San Diego, Cal.

Sattler, R., from 64 W. 7th St. to Groton Bldg., Cincinnati, Ohio.

Thompson, J. H., from 81 Times Bldg. to 403 Deardorf Bldg., Kansas City, Mo.

Wandless, H. W., from Dallas, Texas, to 272 Madison Ave., New York.

Zinke, E. G., from 413 Elm St. to 13 Garfield Pl., Cincinnati, Ohio.

LETTERS RECEIVED.

Akins, William T., Chicago.

Berry, J. T. B., Brandon, Miss.; Baker, L. B., Erie, Pa.; Brown, R. A., Cotton Plant, Ark.; Brown, Mark A., Cincinnati, Ohio; Blackburn, M. H., Dover, Ill.; Bernays, A. C., St. Louis, Mo.; Baldy, J. M., Philadelphia, Pa.; Brannon, L., Joliet, Ill.

THE PUBLIC SERVICES.

Army Changes. Official List of Changes in the Stations and duties of officers serving in the Medical Department, U. S. Army, from February 12 to 18, 1898.

Capt. Paul F. Straub, Asst. Surgeon, is relieved from duty at Angel Island, Cal., and ordered to report in person to the commanding General, Dept. of the Columbia, without delay, for assignment to duty.

First Lieut. Carl R. Darnall, Asst. Surgeon, is relieved from duty at Ft. Clark, Texas, and ordered to Ft. McIntosh, Texas, for duty at that post, relieving Capt. Frederick P. Reynolds, Asst. Surgeon. Capt. Reynolds, on being thus relieved, is ordered to Vancouver Bks., Washington, for duty at that post.

Navy Changes. Changes in the Medical Corps of the U. S. Navy for the week ending February 19, 1898.

Asst. Surgeon G. C. Hubbard, sent to St. Elizabeth's Government Hospital for the Insane.

Asst. Surgeon J. C. Thompson, detached from the naval hospital, Mare Island, Cal., and ordered at once to the "Mohican."

P. A. Surgeon L. H. Stone, ordered to be examined for retirement February 4 and to wait orders.

P. A. Surgeon B. K. Ward, upon completion of temporary duty in New York to proceed home and await orders.

Medical Inspector J. G. Ayers, ordered to assume charge of hospital on Widow's Island in addition to present duties.

Asst. Surgeon H. H. Hans, ordered to the "Vermont."

Surgeon A. C. H. Russell, ordered to duty in the bureau of medicine and surgery February 9.

Asst. Surgeon G. C. Hubbard, ordered home and granted three months' sick leave.

ORIGINAL ARTICLES.

GASTROTOMY FOR THE REMOVAL OF FOREIGN BODIES IN THE STOMACH.

WITH REPORT OF A CASE, AND A TABLE OF REPORTED
CASES OPERATED ON UP TO THE PRESENT TIME.

Read before the Missouri State Medical Association,
at St. Louis, Mo., May 19, 1897.

BY A. H. MEISENBACH, M.D.

PROFESSOR OF SURGERY IN THE MARION SIMS COLLEGE OF MEDICINE.
ST. LOUIS, MO.

INTRODUCTION.

Although gastrotomy for the removal of foreign bodies was performed as early as 1602, it is remarkable to note that from 1602 to 1887, a period of 285 years, only thirty-five cases have been reported as operated on. Many cases of foreign bodies in the stomach, no doubt, were not operated on, and perhaps some have been operated on of which no reports have been made. From 1887 to date twenty-two cases have been reported. Gastrotomy, even in the pre-antiseptic and aseptic period, was a comparatively safe operation, only five out of the thirty-five cases operated on prior to 1887 having proved fatal.

The patients on whom this operation was done were usually either lunatics, or fakirs who swallowed the objects for money.

The indications for the performance of gastrotomy for the removal of foreign bodies in the stomach are: 1, the presence of a body that, on account of its size or form, can not pass through the intestines; 2, the presence of urgent symptoms in the patient.

Foreign bodies may remain in the stomach for a long time without causing serious disturbances, and in some cases their presence may not be known (as in lunatics) until discovered after death by post-mortem. In this respect the form, size, number and weight of the body play an important rôle. Long bodies, such as knives, table forks, spoons, pencils and bars of metal, usually remain in the stomach and give rise to serious symptoms on account of their weight and form. In cases where small objects are swallowed repeatedly their aggregation will eventually, by their weight, favor an accumulation in the stomach and finally may give rise to serious symptoms, producing dilatation of the stomach and local inflammation, adhesions or perforations. That the long continued presence of foreign bodies in the stomach, although tolerated, perhaps, for a long time, will eventually give rise to disturbance of nutrition and other local conditions seems reasonable. There may be symptoms of a catarrhal condition of the stomach, pains in the pit of the stomach and shifting from one spot to another, often influenced by the posture of the patient. When foreign bodies set up subjective

conditions that are progressive in character the patient ultimately grows pale and thin; there may be vomiting, hemorrhage and extreme wasting, eventually ending in exhaustion and death. Where the presence of foreign bodies in the stomach can be established the sooner they are removed the better will be the prognosis, no matter what the character of the body may be.

To the cases that have been reported I have the honor to add the following, which came under my care and observation March 30, 1897. The patient termed himself "The Human Ostrich," and had followed the profession of swallowing glass, metal, etc., for a period of nine years. He presented himself at my clinic, giving the following history:

HISTORY OF THE CASE.

The patient, L. W., "Signor Ranana," aged 22, has the following history:

Family history.—Father and mother living and of very nervous temperament. One living sister.

Previous history.—Patient received a very fair education, attended public high school and college and was within one and one half years of graduation when he left school. While still at school he witnessed, in March, 1888, an exhibition by a professional glass eater. He paid the "Signor" ten dollars to teach him the art of glass-eating. After experimenting for a few days he found he could perform the same feats. At first he gave private exhibitions. He took great interest in swallowing other objects, such as nails, and practiced sword swallowing also. In 1894 he joined a specialty company. At this time he practiced needle and pin sticking (perforating the skin with needles or pins). Since 1894 he has been continually giving private and public exhibitions, at least one or two a week. He does not remember the quantities swallowed. In the early part of March, 1897, he started out on a trip, and on account of scarcity of funds was obliged to give as many as six to twelve exhibitions daily, in saloons and elsewhere, but he did not swallow much at a time, only a bite or two of glass, four or five nails, screws or cartridges, or a few fence staples. He always carried a supply of the objects, so as to be able to give an exhibition of swallowing at any time. In his repertoire were pearl-top lamp chimneys, two-, four-, six- and eight-penny wire fence nails, barbed wire fence staples, and thirty-two and thirty-eight caliber cartridges. He never swallowed tacks.

The patient states that up to 1897 he never had any trouble. He never was sick, nor did he have any trouble with his bowels. On March 15 he gave a number of exhibitions, and on March 16 a "lump in the stomach" and the first pains were noticed. On March 18 the last object was swallowed, a thirty-two caliber cartridge. He came to St. Louis to seek relief, feeling that he was beginning to get into a serious condition.

Present condition.—The patient is 6 ft. 1 inch in height, weighs 153 pounds, has hazel eyes and curly brown hair. His color is pale, gums spongy and breath very foul. He complains of a weight in his stomach, but has no other pains. His pulse is 76, temperature 98 degrees and respirations 23.

Physical examination.—Patient stripped to the waist. Inspection in both upright and recumbent position reveals nothing abnormal. In proportion to his height he ought to be more fleshy.

Palpation and percussion with patient standing upright, body inclined forward, mouth open and abdominal muscles relaxed. In this position palpation and ballottement reveal distinctly a mass situated in the umbilical and hypogastric regions. The mass (tumor) can be raised, and in descent a distinct impulse is felt against the fingers. The mass is about the size of an ordinary hand.

Palpation and percussion with patient reclining on his back

reveals a mass in the umbilical region. Deep pressure clearly outlines the same. Changing the position so that he lies on his right side the mass shifts its position to the right hypochondriac and lumbar regions, and can be clearly defined by palpation. Turning the patient on his left side the mass shifts to the left hypochondriac and lumbar regions. Placing the patient on his back again the mass returns to the umbilical region, and occupies the same position when he arises to his feet.

The manipulations were not associated with any degree of pain, only when deep pressure was practiced the patient would admonish the manipulator to be gentle; it hurt him.

Remarks.—The physical examination alone was sufficient to establish the diagnosis of foreign bodies in the stomach. The patient was willing to have an operation performed, and so was admitted at once (March 30) to the Rebekah Hospital for observation and preparation for the operation. He was placed on liquid diet and orders left to look after the bowels and stools.

The question whether the foreign bodies were located in the stomach or elsewhere was a very important one from an operative and prognostic standpoint. That they were in the stomach was demonstrated to my mind by the constancy of the position of the mass and the position that it occupied. The previous history of the patient was also a valuable point in determining this. The points on which this diagnosis was based were:

1, the position of the mass when the patient was placed in the upright position; 2, the position of the mass when the patient was reclining on his back; 3, the position of the mass when the patient was reclining on his right or left side; 4, the previous history of the patient.

1. The position of the mass when the patient was on his feet or lying on his back. Palpation and percussion demonstrated that it was mostly in the umbilical, but partly in the lumbar region. The mass being a large one and composed, as it was, of heavy objects, the *raison d'être* naturally would be that such a mass would in time have its effect on the stomach and produce dilatation of that part with which it was in contact; gravitating toward the lowest point, this being some part of the greater curvature. Gravitation and dilatation would explain its position in these regions. The only other position that the mass might have occupied would be in some part of the large or small intestine. But this supposition becomes untenable when we critically analyze the possibilities. If the mass had accumulated in the small bowel there would have been symptoms of obstruction and previous history of pain, possibly inflammation. Also, the tumor would not have been as constant in position unless surrounded by inflammatory adhesions that would make a solid, immovable mass. The same would be true of the colon; if in the cecum, we would certainly have had a train of symptoms of either obstruction or inflammation; if in the transverse colon, the position would have been lower. The only other part of the colon would have been the sigmoid or rectum, in either of which the symptoms of obstruction or inflammatory reaction would have been prominent.

2 and 3. Position of mass when patient reclined on left or right side. The constancy with which the mass would shift to the left or right side and return to the median line when the patient was on his back was a strong argument in favor of its location in the stomach. No other location could explain the constancy of position in either region when the patient lay on either side.

4. Previous history of the patient. In establishing a diagnosis this is of the utmost importance. Such a mass accumulated anywhere else in the gastro-intestinal tract would very soon have given rise to very serious symptoms, either of inflammation or obstruction.

Being so firmly convinced that the foreign bodies were located in the stomach, as determined above, other corroborative testimony was hardly necessary. My diagnosis was concurred in by Professors Lemen, Crandall, Bond and others who saw the case afterward. I might have passed a metallic sound into the stomach, passing an electric current through it, but I did not want to do anything that might injure the parts, which might have been done by probing or the reflex vomiting excited by it. However, on April 5 the stomach was inflated with air, so as to more clearly outline its lower border. It was found below the umbilicus, as had already been demonstrated. It was decided, however, to demonstrate, if possible, the presence of the mass by means of the X-rays.

X-RAY EXPERIMENTS.

On Friday evening, April 2, the experiments with the X-rays were made. The apparatus was Thomson's high tension coil 6 inch spark, and was in charge of Dr. Ernest Rubel of the St. Louis Electric Supply Co. The apparatus worked admirably. The fluoroscope was used first. By it the mass could be outlined as a dark spot about four to five inches in diameter. The patient was placed in a standing position with his back to the tube. The position of the mass was the same as revealed in the physical examination, viz., principally in the umbilical region.

A 14 x 17 Cramer, Banner plate, properly wrapped, was placed on a table on which the patient was laid. The plate was so placed that in its area was comprised the abdominal cavity, part of the pelvis and thorax. The exposure was one hour in duration. The X-rays were so powerful that at a distance of six or eight feet from the tube, and on its side or behind it, the fluoroscope showed the skeleton of the hand distinctly. The tube was placed over the abdomen with its long axis parallel with the axis of the body, the center of the tube about over the location of the mass. The distance of the tube from the body was twelve inches; time of exposure for first plate, one hour; second plate, forty minutes.

The plates when developed did not give as good a shadowgraph as was desired. The lumbar spine and the lower part of the thorax were faintly outlined. There was a shadow marking the site of the tumor which, although not as clearly defined as desirable, yet to the practiced eye demonstrated the presence of some foreign body. This shadow was situated a little to the right of the spinal column and in the umbilical region.

Not satisfied with these plates, further exposures were made, the last on Monday evening, April 6, the evening before the operation. Three exposures were made, ranging from thirty-seven to forty minutes each. On development of the plates it was found that the plates of the first exposure were the best, the one exposed one hour being the best of all. The total time during which the patient was exposed to the X-rays at the various sittings, was nearly five hours.

OPERATION (GASTROTOMY).

April 7, 3 P.M., at the Rebekah Hospital, in the presence of the above experiments were made improved methods of technique have made it possible to shorten the exposures to one-half or one-fourth of the above time.

presence of a number of visiting members of the Tri-state Medical Association, and assisted by Drs. Born, Dorsey and others, I performed gastrotomy.

One-half hour previous to the operation the stomach was washed out with a Pasteurine solution. The anesthetic was chloroform.

Incision from the xiphoid to umbilicus was made in the median line, and anterior wall of the stomach presented in the depths of the wound. It was noticed that the stomach was dragged down considerably, so that the superior curvature presented at about the middle of the incision. Introducing my hand into the abdominal cavity I could feel the mass situated below the umbilicus and to the right of the spinal column. The mass was situated nearer to the pyloric end and this part of the stomach was sacculated. Pulling gently on the anterior wall, I was able to draw the stomach out of the abdominal wound to such an extent as to bring the mass into the bottom of the wound area. Grasping the stomach wall with two small, short bullet-forceps, midway between the greater and lesser curvature in the axis of the organ, I made an incision between the forceps into the "cavum" with a knife, the forceps being held by an assistant. Previous to opening the stomach sterilized gauze was packed all around it and into the wound, effectually shutting off the abdominal cavity. The part of the stomach that was extra-abdominal was kept lifted up by the assistant, and was also protected by sterilized gauze.

The opening into the stomach, into which I could look and see the mass, was two inches in length. I introduced a pair of Bergmann calculus forceps and delivered the articles that were on top in the pile of hardware. I continued this operation with the forceps until I felt that its further use might "jab" the sharp articles into the stomach wall. I had provided myself with various shaped spoons, thinking that perhaps they might be of value to scoop out the articles within the stomach. Seeing the sharp nature of the objects, however, I concluded not to use the spoons, but to enlarge the stomach incision and introduce my hand. The wound was enlarged to four and one-half inches, so that my hand could pass freely into the cavity of the stomach. From the first incision (two inches) there was no hemorrhage, and from the last only a little bleeding from the cardiac end of the wound; this was arrested by putting on a hemostatic forceps. With my left hand I scooped out the remaining articles. I worked very carefully so as not to injure the stomach walls, and also not to cut my fingers on the sharp points of the nails, staples, etc., and on the broken pieces of glass. I had expected to find some of the articles imbedded in the mucosa or walls of the stomach. The objects were clean (kept so by the action of the gastric juices). The iron ones were blued and smooth; those of brass and copper (cartridges and chain) of their natural color and bright. There was a thick glairy mucus between them, the mass especially being surrounded by this mucus. During the operation of removing the objects there was continual secretion into the stomach taking place, so that it was necessary, every now and then, to mop it out by means of gauze sponges. The color of the secretion was greenish black.

To satisfy myself that everything had been removed I swept my fingers over the interior of the stomach, especially along the greater curvature, and introduced my index finger into the cardiac and pyloric openings.

Everywhere the mucosa was free from pockets; nor could anything be felt in the stomach walls. Being satisfied that everything had been removed, the interior of the stomach was irrigated with sterilized water, a small quantity being poured in and mopped out with gauze sponges. This operation was repeated several times. Inspection of the mucosa did not reveal any ulcerations, simply abrasions here and there; the membrane seemed somewhat thickened, however.

The stomach wound was closed by three rows of sutures. The first was a strong No. 6 silk, threaded on a straight thick darning needle, and was passed through the mucosa in the form of a continuous suture. The second was of the same silk as the former, a continuous suture, and introduced through the peritoneum and muscular coat, so as to bring the peritoneal surfaces into apposition. The beginning of this line of sutures was one-fourth of an inch from the end of the wound, in the form of a Lembert stitch. The first stitch being tied, the rest of the suture was passed, entering a little more than one-eighth of an inch from the lip of the wound, coming out of the wound and re-entering the opposite lip of the wound. The third row was made with No. 2 braided silk threaded on a straight No. 8 sewing needle. This was a continuous Lembert suture, and completely buried the previous layer of sutures.

The stomach was carefully wiped off with gauze sponges, as was also the abdominal wound. The packing of gauze, which was hardly soiled so carefully had the operation been done, was removed from the abdominal wound, everything again "reviewed," and then the stomach was dropped into the abdominal cavity. There was a strong temptation to lessen the size of the stomach by imbricating a portion of the wall, but I concluded to allow nature to assert herself and correct the dilatation.

The abdominal wound was closed by interrupted through and through sutures. Iodoform collodion was applied over the abdominal sutures, and a cotton pad and a bandage applied.

The time of operation was one hour. The list of articles removed from the stomach shows: Twenty-five staples for barbed fence wire; 15 one and one-half inch screws; 6 two inch horseshoe nails; 16 two inch wire nails; 30 one and one-half inch wire nails; 16 thirty-two caliber cartridges; 5 thirty-eight caliber cartridges; 2 pocket-knife blades (broken); 2 inches of brass wash-stand chain, and 2 small staples; total 119 pieces. Eight cartridges passed after operation. There was also one ounce of comminuted glass (electric light globe); making the total number of objects 127, total weight, one pound.

PROGRESS OF THE CASE.

From the time of admission into the Rebekah Hospital, March 30, to the time of operation, April 7, the records show that the patient complained daily of acute griping pains. Sometimes these pains would recur every fifteen minutes. He was kept on liquid diet and bowels moved by salines and enemata.

Bedside record.—On the morning of the operation, April 7, the patient's temperature was 98, pulse 74.

April 7: 7 P.M., temperature 99, respiration 38, pulse 72; belching considerable gas; 9:45 P.M., temperature 99.5, respiration 34, pulse 114; one-thirtieth strychnia given hypodermically.

April 8: 12 A.M., temperature 100, respiration 34, pulse 90; 10:30 P.M., temperature 99.4, respiration 30, pulse 86. Vomited some dark slimy matter, about 3 ozs.

April 9: 12 A.M., temperature 99, respiration 30, pulse 96;

10:30 P.M., temperature 100, respiration 28, pulse 86; vomited dark green slimy liquid.

April 10: 1 A.M., temperature 98, respiration 28, pulse 86; 2:15 P.M., temperature 101, respiration 30, pulse 88. Coughing; inhalation of finct. benzoin and chloroform. Calomel gr. 1 every hour for eight hours. Examination of lungs posteriorly reveals coarse râles in right lung; 4:15 P.M., temperature 102, respiration 30, pulse 88.

April 11: 1:15 P.M., temperature 101.6; respiration 28, pulse 90; 7:35 P.M., temperature 102, respiration 27, pulse 86. Examination of lungs by Professors Lemen and Crandall revealed pneumonia of right lung with solidification at base.

April 12: 12 A.M., temperature 101, respiration 26, pulse 82; 2:15 P.M., temperature 102, respiration 30, pulse 88; 8 P.M., temperature 102, respiration 30, pulse 90.

April 13: 8 A.M., temperature 100, respiration 32, pulse 88; 12:15 P.M., temperature 101, respiration 30, pulse 88; 9 P.M., temperature 101, respiration 30, pulse 88.

April 14: 8 A.M., temperature 101, respiration 28, pulse 90; 4:45 P.M., temperature 101.3; respiration 28, pulse 90.

April 15: 8 A.M., temperature 100.3, respiration 22, pulse 86; 2:30 P.M., temperature 101, respiration 22, pulse 86; 8 P.M., temperature 100, respiration 22, pulse 84. Wound was dressed today. The stitches, which were loose, and the colloid dressing were removed. The bridges of tissue between the stitches seemed to be united. The wound was macerated under the dressings and a large area of epidermis around the wound was exfoliated. A pad of gauze was placed over the wound and over this adhesive strips, taking a good hold on either side of the wound (passed halfway around the body).

April 16: 8 A.M., temperature 100, respiration 24, pulse 84; 4:30 P.M., temperature 100, respiration 24, pulse 86. Wound had discharged very much so that dressings were soaked. On removing the dressings and plaster I found that the parietal wound had become torn open and was gaping. The peritoneum, however, was intact, with the exception of the lower angle, at which there was an omental protrusion about two inches long and one and one half inches at the base. The wound was carefully cleansed with sterilized water and firmly packed with iodoform gauze, the gauze being so placed as to surround the protruding omentum so as to isolate it from the rest of the wound. No bad effects seemed to follow the opening of the wound.

April 17: 1 A.M., temperature 101, respiration 24, pulse 86; 12:15 A.M., temperature 99.5, respiration 22, pulse 84. Wound dressed and packed as on previous day.

April 18: Condition as on previous day. Wound dressed.

April 19: 8 A.M., temperature 100.2, respiration 34, pulse 84; 4:15 P.M., temperature 100, respiration 22, pulse 84. Wound dressed.

April 20: 8:30 A.M., temperature 100.2, respiration 24, pulse 90; 4:30 P.M., temperature 99.3, respiration 22, pulse 84. An elastic ligature was thrown around the base of the omentum so as to strangulate the protruding portion, having waited until now so as to get firm adhesions to the peritoneum. The only inconvenience caused by this protrusion was nausea at times.

April 21: 8 A.M., temperature 98.4, respiration 22, pulse 84; 5:30 P.M., temperature 100, respiration 22, pulse 86. Omental stump contracted, circulation cut off; twisted ligature tighter; wound repacked.

April 22: 8:15 A.M., temperature 100, respiration 22, pulse 86; 5 P.M., temperature 99, respiration 20, pulse 82. Dressed and packed wound. Cut off the omental tumor, first tying a heavy silk ligature around it.

April 23: 10 A.M., temperature 100, respiration 22, pulse 80.

From this time on the temperature varied from normal to 99.5 degrees F., the pulse from 76 to 80, and respiration from 16 to 20 per minute.

With the general improvement the lung also became cleared up, so that by May 1 all symptoms of consolidation had passed off. The wound is closing up fast by granulations.²

REMARKS.

The object in giving the details of this remarkable case is to call attention to several peculiarities. 1. The pneumonia. 2. The non-union of the wound and blistering of the skin.

² The usual rules as to feeding after laparotomy were observed: No food or drink for first twenty-four hours; then liquids, liquid peptonoids, malted milk. After ten days, oatmeal and solid food. Pneumonia was treated expectantly, free stimulation, etc.

From the bedside record given above it will be noted that the patient promptly recovered from the shock of the operation; in fact, there was practically no shock at all. On the evening of the day of operation his pulse ran up to 114, temperature, 99.4 degrees, respiration 34, and the condition of the pulse, respiration and temperature during the first three days after the operation shows a perfectly aseptic, normal course. On April 10 it is noted that the patient coughed, and an examination of the lungs indicated congestion. The day following, April 11, examination by Profs. Lemen and Crandall revealed solidification of the lung on the right side. Referring to our bedside record we find the following: 1 A.M. temperature 98 degrees, respiration 28, pulse 86; 2:15 P.M. temperature 101 degrees, respiration 30, pulse 87; 4:15 P.M. temperature 102 degrees, respiration 34, pulse 88.

The patient had no chill, nor did he have much pain. The coughing caused him some pain, but there was no expectoration of pneumonic sputum. Here we have the evidences of a hypostatic pneumonia, although with atypical symptoms, especially when we note the respiration and pulse, a temperature of 102 degrees, and pulse not above 96. Usually, when inflammatory or congestive conditions of the lung supervene with a rise of temperature there is a concomitant rise of pulse, so that with a temperature of 102 degrees we would expect a pulse rate considerably above 100; that has been my experience. The interesting feature about this question is, what caused the pneumonia? It is possible to have hypostatic pneumonia following surgical operations, in cases that are debilitated. It may follow in any case of sickness of long duration where the nutritive powers are below par. Yet I have never had it occur in my surgical practice.

What part did the X-ray play in its production? This question I can not answer positively, only in a conjectural way. It will be noted that the patient was exposed several times, the exposures varying from thirty minutes to one hour. Including the use of the fluoroscope, he was exposed perhaps five hours in all. The conditions, such as chilling the patient, under which the exposures were made might have been a factor in causing the pneumonia. The room in which the exposures were made was of average temperature, 70 degrees F. The patient was exposed having on only a thin undershirt, with lower limbs enveloped in a blanket. The first exposure was made on April 2, five days before the operation and eight days before the first symptoms of the lung complication arose. The last exposure was made the evening before the operation, and four days before the complication arose. The above facts would not bear out the argument that exposure of the patient to changes of temperature caused the pneumonia, because we know that where exposure is a factor in producing pneumonia the onset is rapid, usually ushered in by a chill, increased temperature and high pulse-rate. I can not imagine a pneumonia, such as our patient had, with its atypical symptoms, to follow exposure; so that I believe we can exclude this argument. The only one left would be that the X-rays were the cause.

The extensive use of the X-rays develops the fact that under certain conditions they are not as harmless as may be supposed. Reports of cases of burns of the integument are received. Two have occurred in the Rebekah Hospital, not in my service, however. It is reported that depilation and periostitis occur. These

54 1896	Jour. Amer. Medical Asso., Feb. 1, 1896.	Allen, Haven- port, Iowa.	Maggie Hitchz. F. 16.	Hairball, length 9 1/2 inches, circumfer- ence 8 1/2 in.	More or less pain after eating; vomiting frequent; emula- tion; alternating diarrhea and con- stipation.	Incision in median line, from ensiform cartil. down below umbilicus; stom. felt, look, parallel to greater curvature; hairball removed with dif- ficulty; stom. wound sutured in two layers; mucous membrane continuous silk; serous interrupted Lembert.	Codoln, 1 1/2 gr. hypodermically; milk, liquid pep- tonoids per rec- tum; peptonized milk by mouth 6th day; stitches removed 7th day; union by first in- tention.	Recovery; discharged cured on 29th day.	Patient was in the habit of biting off ends of hair since 3 years of age; felt tumor during last five or six years, but it did not increase in size apparently.
55 1896	Annals of Surg., April, 1896, p. 415.	Morton, Bristol.	M. 27.	Plate with 2 up rincisors		None.	None.	Death, 8th day.	Swallowed accident- ally; death from local suppurative periton.
56 1896	Centralb. f. Chir., No. 1, 311, Bericht über den Congress, No. 24, 1896.	Stelzner.	F. 18.	Hairball size of goose egg wt. 180 gms.		None.	None.	Recovery.	Habitually bit off the ends of own hair and that of other girls.
57 1897	Deutsche Medicinische Wochenschrift, Jan. 24, 1897.	Fricker, Odessa.	Mrs. A. F. 32.	Articles swal- lowed, 2 iron fork, 2 spec- tacles, 2 hair- pins, 12 spec- tacles, 1 win- dow latch, 1 steel pin, 1 point, 1 sew- ing needle, 1 piece of graphite, 1 small shuttle, 1 grape- seed, 1 cro- chetting needle.	At first slight incon- venience, loss of ap- petite, slight pain, gradual emaciation. All remedies with- out curative effect. Later all symp- toms in such aggra- vated; marked swell- ing in left side from margin of ribs to rim of ilium; fluctuating and very tender; vomiting and consti- pation.	Incision over swelling, evacuation of pus and withdrawal of crocheting needle; other arti- cles detected in stomach; abdominal incision enlarged, stomach drawn out and incision made not connecting with abscess; incision 4 cm. long, near lesser curvature; all bodies re- moved without difficulty, except fork; stom- ach sutured, 2 rows; mucous, caecum, serous, interrupted Lembert silk; abdominal wound packed with iodoform gauze until fifth day, then closed with secondary suture.	Nourishment by enema during first five days; later, carefully regulated diet per os; temper- ature never above normal.	Recovery in 4 weeks.	Articles swallowed during attack of temporary insanity from loss of child, and with a view to suicide.
58 1897	Unpublished.	Von Quast, Kansas City, Mo.	M. 35. Showman.	Nine drams for kengles, 2 pocket knif- es, 5 knife blades, 1 barbed scaple, 3 screws, 1 horse-shoe nail, 16 tacks of all sizes, 4 finishing nails, 1 12- penny nail, 55 wire nails of sizes 4 to 12.	Emaciated, suffering from want of food and retching.	Incision ensiform to umbilicus; stomach incised so as to introduce forceps and finger; stomach wound closed by inter- rupted Lembert sutures.	None of stom- ach; some of the for- eign bodies to the mucosa.	Death in 48 hrs. from enteritis and ex- haustion.	Patient was in wret- ched condition, but demanded relief. Possibly long-expos- ure to X-rays to diagnose the con- tents of the stomach and relieve our minds of "fakirism," but something to do in the production of enteritis or periton- itis. There had been considerable bema- nism and blood- passing from bow- els.

NOTE.—The last case came to hand too late for classification at the time paper was read.

I wish to acknowledge the very valuable assistance rendered by my colleague Dr. W. H. Fuchs, in the tabulating of the cases of gastrotomy for foreign bodies herein given.

effects are not immediate, due to the heat of the electric current, but are remote in their manifestation, occurring sometimes five to ten days after the exposure. This being the case, there must be some effect of the X-rays on the tissues. Sorel, a French surgeon, recently made the statement, in a paper before the Havre Lyceum, that pneumonia can be produced by the X-ray. Having seen this statement in a cablegram from Paris, I wrote W. W. Keen about the case, because his extensive experience in X-ray work makes his opinion authoritative. According to Keen, Sorel is a French provincial surgeon whose statements are trustworthy. Keen also concurred in the opinion that it is possible to produce pneumonia by the X-ray.

Another argument in favor of the assumption that the X-ray caused the pneumonia is the fact that the pneumonia occurred on the right side, and the X-rays were directed principally over this side, because the mass was somewhat to the right of the spinal column when the patient was in the reclining posture.

The non-union of the wound is also an interesting question. In surgical wounds non-union may be due to the following causes: 1, faulty coaptation; 2, strains on the wound, 3, sepsis, 4, certain states of the system, such as extreme jaundice, etc.

The first, third and fourth conditions can be excluded entirely. It might be argued that patient's straining while coughing might have produced it. This might be true, but I have had patients in whom bronchial irritation before the operation (laparotomy) caused coughing spells afterward and, still, union took place. In these cases the precaution was always taken to support the wound by the application of adhesive strips around the body. It has been noted that when the stitches were removed the parts were macerated under the loose epidermis. This does not occur in normal wounds. The history is the strongest argument in support of the theory of the effect of the X-rays. In the cases reported the effects were always remote, as in this one.

Although I can not prove the statement at present. I believe that the complications in this case were due to the X-rays, an X-ray pneumonia and non-union of the wound. The *modus operandi* of the X-rays in these complications is, I believe, that they cause a vaso-motor paralysis, producing a dilatation of the vessels, from which cause local stasis results.

To my knowledge this case is the first on record in which the X-rays have been used to demonstrate foreign bodies in the stomach. Fricker, of Odessa (see case in table), was deterred from using them in his case on account of the extreme weakness of his patient. Fricker's and my case are the only ones reported of gastrotomy for the removal of foreign bodies, since the discovery of the X-rays. This case is also the first reported, in this country, of pneumonia following the application of the X-rays.

POINTS OF INTEREST.

The points of interest in this remarkable case are: 1. The period of time during which the patient has been swallowing objects. 2. The number of bodies found in the stomach. 3. The character of the objects found. 4. The absence of serious subjective symptoms in the patient, and the absence of serious pathologic conditions in the stomach. 5. The complications after the operation, due to the X-rays: *a*, pneumonia; *b*, non-union of the wound. 6. The first case of pneumonia due to the X-rays reported in this

country. 7. The first case, on record, of foreign bodies in the stomach on which the X-rays were used to corroborate a diagnosis.

SUMMARY.

Summarizing the data contained in the foregoing table, we have the following:

Total number of cases reported to date, 58. Of this number there were forty-seven recoveries or 81.03 per cent.; ten deaths or 17.24 per cent., and one doubtful, or 1.73 per cent.

Of those cases in which no adhesions of the stomach to the abdominal walls or surrounding viscera were present, thirty-eight in all, there were thirty recoveries, or 78.95 per cent.; seven deaths or 18.42 per cent.; one doubtful or 2.63 per cent.

Of those cases in which adhesions were present, thirteen in all, there were eleven recoveries, or 84.62 per cent.; two deaths, or 15.38 per cent. Of those cases in which the existence of adhesions was doubtful, seven in all, there were six recoveries or 85.72 per cent.; one death or 14.28 per cent. It will thus be seen that the existence or absence of adhesions had, apparently at least, no influence on the mortality rate.

Assuming that the period of antiseptic surgery began with the year 1880, and dividing the reported cases into two groups, i.e., those reported before 1880, and those reported since that date, we have the following exhibit of mortality percentages. 1. Before the introduction of antiseptics: Total number of cases eighteen; recoveries fifteen or 83.33 per cent.; deaths three or 16.66 per cent. 2. After the introduction of antiseptics: Total number of cases forty; recoveries thirty-two or 80 per cent.; deaths seven or 7.50 per cent.; doubtful result one or 2.50 per cent.

A noteworthy fact in connection with the cases enumerated in the table is the short period intervening between the entrance into the stomach of the foreign body or the diagnosis of its presence there, and the performance of the operation, during the period since the introduction of antiseptics. This is probably attributable to two factors: 1. The improved methods and facilities for making diagnoses; and 2, the improvement in surgical technique and the extension of surgical interference since the introduction of antiseptics. Taking into consideration all the cases contained in the table, however, we find that the time intervening between the introduction of the foreign body into the stomach and its removal, is definitely known in only so few cases, that its consideration as a factor of possible influence on the mortality rate would be entirely unsatisfactory. It has, therefore, not been considered separately.

The following is a summary of the foreign bodies removed from the stomach by operation:

Forks in thirteen cases; hairballs in seven; knives in six; plates with teeth in six; spoons in five; pieces of wood in four; pieces of metal wire in four; nails in four; buttons in three; needles in three; tooth brushes in two; safety-pin in two; peach-stones in two; and screws, bar of lead, piece of earthen ware, tracheal catheter, metal probang, part of sword-blade, clay-pipe stem, razor, pocket-knives, hair-pins, pieces of glass, keys, window latch, piece of graphite, and tacks in one case each.

REMOVAL OF THE STOMACH FOR SARCOMA.

BY J. M. BALDY, M.D.
 PHILADELPHIA, PA.

The JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, Feb. 12, 1898, contains an article by Hugo Summa, M.D., and A. C. Bernays, M.D., entitled "The History and Diagnosis of a Case of Carcinoma of the Stomach and the first Operation of Excision of the Stomach in America."

In view of this report it may be of interest to recall a case of sarcoma of the stomach for which excision of that organ was performed by me more than four years ago, antedating some years the now famous case of Schatter of Zurich.

The case is well known in Philadelphia among my medical friends and has on several occasions been referred to in discussion on abdominal topics. The patient was examined by Dr. S. Solis-Cohen and I think Drs. T. S. K. Morton and Steinbach of the Polyclinic staff. Dr. John B. Roberts and other members of the staff were present at the operation. I was assisted by Dr. Frank Talley and one of the resident physicians of the hospital.

The case was reported and the specimen shown to the Pathological Society of Philadelphia by Dr. Alfred Stengel and myself. After careful investigation Dr. Stengel pronounced the case one of sarcoma of the stomach, an exceedingly rare condition. He requested the privilege of reporting the details of the case after he had thoroughly looked up the literature of the subject. I handed him the surgical notes to incorporate in his paper, which he informs me is ready for publication and will be shortly forthcoming. I might mention incidentally that he has been able after four years search to find in the literature but nine cases of a similar character (sarcoma of the stomach).

I append the surgical notes of the case which I handed Dr. Stengel four years ago to incorporate in his article and which he has kindly returned to me.

The patient entered the Polyclinic hospital Sept. 29, 1893 complaining of a tumor in his stomach together with great and progressing weakness and loss of flesh.

An examination disclosed an irregular rounded, nodular and solid tumor filling the whole abdomen from the pubes to the ensiform cartilage. The umbilicus protruded and contained a neoplasm which was unattached to the underlying tumor, about the size of a walnut. The pelvis was free and the tumor rested on the pubic bones; the fingers could easily be passed between the tumor and the pubes. As far as could be determined from the history and examination the kidneys were excluded as a possibility of the origin. The urine was normal. The spleen was likewise excluded, as was also the liver. A diagnosis of malignant tumor was easily arrived at from the nodular, irregular feel of the mass, its quick growth, the rapid loss of flesh and weakness and cachexia of the patient and the umbilical growth. By exclusion it was supposed to be a growth of either the mesenteric glands or of the omentum. If of the mesenteric glands operation was hopeless; if of the omentum some hope existed, especially

as the tumor was freely movable. The chances were given to the omentum on account of this very invariability and because the history showed that it had begun to grow from above downward. It was even at that time easy to determine that its attachment was above. The case was seen in consultation by the medical and surgical staff of the hospital and all agreed that the only chance of life lay in an exploratory operation and further that such exploration was justifiable. The friends of the family were communicated with and the facts placed before them. They were told that no promise could be given that the man would even come off the operating table alive, but that in an operation lay his only chance. They decided for the operation.

The stomach as a possible source of origin of the tumor was never considered for the following reasons. His bowels had to the last remained in good condition. He had never at any time complained of gastric disturbance of any kind; as he expressed it "my stomach has never given me a day's trouble, it is the strongest thing about me." In proof of the truth of his statement it is to be noted that he spent about a week in the hospital prior to his operation, ate voraciously and digested all he ate. At the time of the operation the stomach cavity was found practically empty. He never vomited.

An incision was made from the ensiform cartilage to near the pubes and the abdominal walls drawn apart. They grasped the tumor tightly as they slipped over its sides and contracted again under the tumor as it was delivered. In doing so many vessels in the omentum, which was spread out over the tumor and adherent to it, began to bleed. From this moment to have ended the operation would have been difficult, as the bleeding could only with difficulty have been controlled nor could the tumor have again been returned to the abdominal cavity and the abdominal wound closed; the operation had to be finished at all hazards. The tumor was lifted up from below and found adherent to all the underlying intestines; these adhesions were readily separated; freeing the tumor in all directions but leaving the mesentery infiltrated with masses of malignant growth. The utter hopelessness of the case was at once seen. The separation of the mass was continued as high up as possible, to a point which afterward was found to be the natural attachments of the stomach. What appeared to be the healthy stomach was found high up and in front closely attached to the tumor apparently in much the same way as had been the intestines beneath. At this point the common consensus of opinion of the surgeons operating, assisting and looking on was that the growth arose from behind the stomach; no suspicion as to its being the stomach being entertained by any one. An effort was made to separate the apparent stomach and the tumor at their point of adhesion but was soon desisted from on account of the danger felt of perforating the stomach wall itself if I worked too near it. The determination was then made to break boldly into the tumor several inches below its junction with the stomach, leaving part of it attached to that organ, remove the balance and thus gain room enough to close the abdomen and finish the operation. A favorable point was fixed upon where there was a sulcus and a finger was forced into the mass and swept freely from side to side. After proceeding for the depth of some inches the finger suddenly entered a cavity and in a moment the whole situation flashed upon me. With several fingers in

the cavity a bimanual examination quickly made my suspicions a certainty. The tumor was the stomach. The only healthy part of the organ was the small anterior portion presenting at the upper part of the wound and which had been mistaken for the lower part of the whole organ. This proved to be a portion of the anterior part of the cardiac end. I accepted the inevitable at once, continued my dissections, removed all the large mass and quickly ligating bleeding points made an effort to form a pretense of a stomach of the small piece remaining of cardiac end, esophagus and gut, and closed the wounds. The patient lived about thirty-six hours, complaining of both hunger and thirst. He was given morphia hypodermically in sufficient quantity to keep him easy until his death.

All but a small portion of the stomach was involved as was also the mesentery throughout the whole abdomen. A large mass of disease was left high up and involving the esophagus. The omentum was not invaded.

From the manner in which this patient stood the shock of the manipulation I had no doubt at the time and have none now but that had there been sufficient healthy tissue at the esophagus to have allowed of a successful attachment of the gut to that canal the result would have been different. The whole posterior and lateral walls of the stomach up to, and extending some distance up the esophagus were involved. There was about two or three inches of the anterior stomach wall at the end of the esophagus comparatively healthy, but the conditions were such as to render my efforts to form a continuous canal futile.

GONORRHEA.

A Clinical Lecture to Members of the American Medical Association
Delivered in the Medico-Chirurgical Hospital of Philadelphia.

BY JOHN V. SHOEMAKER, M.D., LL.D.

PROFESSOR OF SKIN AND VENEREAL DISEASES IN THE MEDICO-CHIRURGICAL
COLLEGE AND HOSPITAL OF PHILADELPHIA.
PHILADELPHIA, PA.

ACUTE GONORRHEA.

This young man has suffered from acute gonorrhea for six days. It is his first attack. The period of incubation was three days. There is an abundant discharge and intense pain on micturition. The prepuce and scrotum are greatly swollen.

A second man presents analogous symptoms and history. Four days after exposure he was attacked by sharp, stinging pain upon passing urine. A discharge, thin at first but which rapidly became thick and copious, soon developed. The disease has now been fully established for five days. There is some tenderness in both testicles and he has been troubled by chordee.

There need seldom be any difficulty in the diagnosis of gonorrhea. The muco-purulent discharge excited by the presence of a urethral chancre is sometimes sufficiently abundant to simulate gonorrhea. A chancre in that situation, however, can be readily recognized by the induration which it produces. The purulent flow in pyelitis may be so constant and profuse as to resemble a gonorrheal discharge. In pyelitis we have a history of pain in the back, febrile movement, vomiting and attacks of nephritic colic. The escape of pus in pyelitis is unaccompanied by urethral pain.

Gonorrhea is an exceedingly common disease and all are familiar with its ordinary manifestations, com-

plications and consequences. Its rapid extension along the urethra, the inflammatory engorgement and edema, the chordee, phimosis, paraphimosis, balanoposthitis, epididymitis and arthritis by which it may be accompanied, are features presented to our notice every day. There are certain less frequent phenomena which we should bear in mind as regards this disease.

Gonorrhea attacks indifferently any mucous membrane with which its virus comes in contact. We must not allow ourselves to be deceived by the unusual characters of some cases which we are called upon to treat. The victims of gonorrhea, acquired in the usual way, are generally frank to the extreme in their confessions. It is otherwise, however, with those who have participated in unnatural practices. In such cases we are ordinarily compelled to rely upon our own sagacity. If a suppuration of a mucous membrane is abrupt in its onset, virulent in its nature and destructive in its effects, we would be warranted in at least suspecting the influence of gonorrhea. Light may be thrown upon the case also by the occupation and habits of the patient. Gonorrhea of the rectum may occur either from the abundance of the discharge and the transmission of, particularly, a vaginal infection to the anus and rectum or it may result from sodomy or pederasty. The ophthalmia excited by contact with gonorrheal virus in the child during birth or in the adult from gross carelessness, is a not infrequent incident. Gonorrhea of the nose may arise from similar circumstances. Edwards observed a case of a widow 60 years of age, who was affected by blowing her nose in the suspensory of her son who was suffering from gonorrhea. Other cases of nasal infection have been reported. In acute cases the nose becomes enormously swollen and the skin red, shining and painful. The face and upper lip are likewise tumefied. There is an abundant discharge, which causes ulceration of the lip. Ziem and Cozzolino are disposed to admit that the purulent rhinitis of the new-born may, like the purulent ophthalmia, be a manifestation of gonorrheal infection acquired during birth. Gonorrheal infection is sometimes encountered in adults as a result of unnatural vice.

During the second stage, inflammation sometimes spreads from the posterior urethra to the follicular structure of the prostate gland, causing a painful enlargement and obstruction to the outflow of urine. This acute prostatitis usually terminates in resolution, though suppuration may occur. At the same time the neck or fundus of the bladder may become involved. In other cases the disease extends to one or both of Cowper's glands, giving rise to much throbbing pain. The deferentia and vesiculæ seminales may likewise be attacked. The former is recognized as a hard, thickened, painful cord, occupying the position of the inguinal canal. The seminal vesicle is swollen and painful.

Since the demonstration of the gonococcus as the active cause of gonorrhea our knowledge has become more exact as regards the constitutional complications which sometimes take place. A formidable list of such occurrences has gradually accumulated. Prior to the discovery of the microbe the septic origin of "gonorrheal rheumatism" had been suspected. This not unusual complication is now brought into more intelligible relation to the primary disease. Suppurative arthritis is occasionally observed in consequence of gonorrhea. In connection with this subject it is of interest to note the study by M. Achard of gonorrh-

eal arthritis by means of the Roentgen rays. In a patient who had had several attacks of gonorrhea, each being complicated by articular trouble, considerable deformity of the bones of the toes was found. The periosteum and bone were both affected, and in one spot an osteophyte was observed. Inflammation of the crico-arytenoid articulation of the larynx has been seen as a result of gonorrhea.

Of late years quite a number of cases of endocarditis due to gonorrhea have been reported. Prof. Albert Abrams of San Francisco has related the history of a boy 17, who on the fourteenth day of a gonorrhea was attacked by cardiac manifestations. There was distressing tachycardia with a feeble systolic murmur over the aorta and an increase in the area of superficial cardiac dulness toward the right side. Two days later the patient died. The endocarditis had not been preceded by gonorrheal rheumatism; the previous history of the lad was one of perfect health and absolute integrity of the heart. Dr. Siegheim has recently reported a fatal case of ulcerative gonorrheal endocarditis. Arthur Loxton has placed upon record a case of death, apparently due to acute septicemia in a patient afflicted with gonorrhea, the fatal issue taking place about a month after the venereal disorder had been contracted. Another fatal case was observed by M. Combemale. After gonorrhea had lasted for two months infectious rheumatism of several joints supervened. A few days later nephritis developed and the generalized infection was suddenly terminated by purulent bronchitis and parotiditis.

Pleurisy has been witnessed during the course of gonorrhea. This complication is usually mild, of short duration and may either be dry or attended by effusion.

Myelitis, paraplegia and muscular atrophy have been reported as consequences of acute gonorrhea. Professor Pitres has published an account of a patient suffering from acute gonorrhea who had painful swelling of some joints on the day after admittance to the hospital, and who later in the same day was attacked by right-sided hemiplegia and coma. Six weeks later he was seized with Jacksonian convulsions, in which he died. A very extensive softening was found in the region of the Sylvian artery but no atheroma could be discovered.

In the female, gonorrhea lays the foundation of a series of the gravest ailments of the womb, tubes and ovaries. We should therefore be deeply impressed by the fact that in neither sex is gonorrhea a disease to be lightly esteemed. We have learned that in its immediate and ulterior consequences it is a most prolific source of physical suffering and mental unhappiness.

Returning to the patients, victims of ordinary, every-day clap free from complications, we should wish to direct their treatment in such a manner as to safeguard them as far as we may against the development of possible complications and sequelæ. The more successful our management now the better the outlook for our patients' future. Since the discovery of the gonococcus, the renewed study of the natural history of gonorrhea as an infection and the general adoption of antiseptic methods, we are prompted to ask ourselves whether any improvements upon the older modes of treatment have been devised.

The chief aim of treatment is to destroy or paralyze the bacteria, or at least counteract their virulent products. The time honored blennorrhetics and injections possess a certain degree of germicidal and antiseptic

power. Have we gained any new remedies or learned any new procedures by which we shall be able to hasten and perfect a cure? Gonorrhea has been acknowledged a difficult disease to cure permanently, as for a considerable period after all discharge has been suppressed a relapse may occur upon slight provocation.

One drug brought into use in recent years has proved a meritorious addition to our armamentarium, viz., salol. A combination of salicylic and carbolic acid, salol must evidently possess valuable antiseptic properties. In its escape from the system it exerts a beneficial effect upon the urethral mucous membrane. A second drug which acts in a similar manner in these cases is terebene, a derivative of turpentine. I am much in the habit also of prescribing in acute gonorrhea small doses of belladonna, which has a good influence upon the urethral glands.

For the first patient I shall order terebene, to be given in 0.31 c.c. increasing to 0.62 c.c. doses four times a day. On account of the edema he shall also have 0.06 increasing to 0.12 c.c. every two hours, of tincture of aconite. The second patient shall take 0.32 gram of salol, combined with 0.12 c.c. of the tincture of belladonna and 0.31 to 0.62 c.c. oil of sandalwood four times a day. For the erections I shall order a suppository containing 0.016 gram extract of belladonna with 0.32 gram of monobromated camphor. As regards local treatment I shall adopt what is known as Janet's method. This consists in the copious irrigation of the urethra and bladder with a 1 to 1000 or 1 to 2000 solution of potassium permanganate, a quart or more of the fluid being passed in at each sitting and the operation practiced every day for ten days or two weeks. The solution is made to flow by gravity from a large receptacle through a rubber tube connecting with an ordinary urethral syringe. This procedure is much more efficient in removing inflammatory products from the urethral crypts than the old practice of small and repeated injections made by the patient or even by the physician.

In association with the medical treatment I lay great stress on repose of body and mind, abstinence from liquors, highly seasoned foods, etc.

CHRONIC GONORRHEA.

I have likewise present three patients in whom gonorrhea has become chronic. The first man is 28 years of age. He contracted the disease ten months ago, submitted to treatment for about a month and was nearly free from discharge. Becoming impatient of the restrictions imposed upon him he then "threw physic to the dogs" and abandoned himself to a careless life. Since that time he has almost continually been afflicted by some degree of urethral leakage. At times it would almost disappear; then some imprudence in eating or drinking, exposure to cold or venereal excitement would cause a return of the flow. He comes here today in one of these periods of recrudescence. The discharge is moderately abundant and distinctly purulent. There is some pain on passing urine. During his intervals of comparative freedom he sometimes sees no discharge for several days; then he will perceive a few drops of thick pus escape from the meatus in the morning, or he can express it from the urethra when some hours have passed since the act of micturition.

A second man, 27 years of age, had a first attack of gonorrhea five years ago, and eighteen months ago he contracted a fresh case. The latter was undoubtedly

due to re-infection, as it began four days after impure connection, was accompanied by a free discharge, pain in the urethra, swelling of the penis and complicated by epididymitis. Six weeks ago the man again cohabited for the first time since his second attack, and for two weeks indulged freely in intercourse. The result was a return of discharge, which is now rather abundant.

A third patient is 40 years of age. Eight months ago he contracted gonorrhea for the third time. He appeared to recover entirely and was untroubled until a few days ago when a dietetic excess brought back a scanty discharge.

These cases illustrate the difficulty of obtaining a radical cure of gonorrhea, the persistence of a slight discharge and the readiness with which an exacerbation is excited. From the medical point of view there are two features of special interest connected with chronic gonorrhea. One is the danger of communicating the disease, the second is the tendency to the formation of stricture.

We understand the subject of the transmissibility of gonorrhea better now than we did a few years ago. The study of gonococcus has cleared our conceptions. What formerly could be only a suspicion or belief founded upon clinical evidence can now be made an objective demonstration. From bacteriologic study we now know that the microbes long survive in the urethral crypts and cells, that however attenuated they may become they remain susceptible, under favorable circumstances, of reviving into activity. Deposited upon the mucous membrane of the female genital tract they are capable of exciting a gonorrheal catarrh which, though often more insidious than an acute attack, is followed by a more permanent and injurious effect.

It is scarcely possible, under the older and ordinary methods, to wash out thoroughly all the folds of the male urethral mucous membrane and to dislodge effectually the bacteria and inflammatory products. Consequently at one or more points along the canal inflammation lingers and bacteria survive. These spots are, on the one hand, starting points for exacerbations and relapses and, on the other, they are the first steps in the process of formation of strictures. These spots or patches are somewhat rough and often more or less completely denuded of epithelium and hence the name, "granular patches," by which they are known. The urethra at these places is morbidly sensitive, as is proved by the passage of a soft bougie. The low grade inflammation causes proliferation of the subjacent fibrous tissue. With the progress of time this tissue fulfills its law of contraction and the result is a gradual but progressive narrowing of the lumen of the urethra and a corresponding impediment to the exit of urine. Urethral stricture has a literature and surgery of its own and I have no time for comment upon such a broad subject. The prime consideration is that by well directed efforts in the acute stage and by local applications to the granular patches we may minimize the production of strictures.

I find upon examination that each of these three men has at least one granular patch upon the wall of the urethra. The second patient has two such lesions. The first patient is suffering now from what is almost equivalent to an acute clap. In his case I will have carried out a treatment applicable to the acute disorder until the manifestations have subsided, when I shall have recourse to direct medication of the

patches in the same manner as in the other two cases. This method employs a syringe which holds 0.92 or 1.23 c.c., attached to a flexible catheter, which terminates in a bulbous nozzle. The solution to be used is placed within the syringe, the granular patch is located by means of the *bougie à boule* and the medicated fluid can then be deposited exactly upon the surface of the lesion. Before performing this operation the bladder of the patient should be evacuated. An application of this kind is made two or three times a week. This is a procedure to which I often resort with very satisfactory results. Various substances may be used. I often apply in this manner a solution of silver nitrate, beginning with a strength of 0.32 to 0.65 gram to 29.5 c.c. water and gradually increasing according as it is tolerated. Copper sulphate also makes an excellent application and this is the remedy which I shall use today, taking first a 5 per cent. solution and increasing the proportion to 10 per cent.

LECTURES ON TUBERCULOSIS OF THE KIDNEY.

BY CHARLES GREENE CUMSTON, B.M.S., M.D.

Assistant Professor of Surgical Pathology, Faculty of Medicine, Tufts' College, Boston; Fellow of the American Association of Obstetricians and Gynecologists; Corresponding Member of the Association of Genito-Urinary Surgeons of France, of the Pathological Society of Brussels, of the Electrotherapeutic Society of France, etc.

BOSTON, MASS.

LECTURE I.

Tuberculosis of the kidney occurs in two forms, viz., miliary granulations and tuberculous infiltration of the kidney. The first form is a medical tuberculosis, while the second is more or less surgical.

Durand-Fardel has described a special form of renal tuberculosis. He saw a case in which he found great quantities of bacilli but which had not produced any pathologic change in the kidney; the glomeruli contained Koch's bacillus in their capillary loops, but the organism had not had sufficient time to produce irritative lesions, for all the renal tissue was found normal, even the structure of the glomeruli was healthy. Some vessels which were packed with bacilli to such an extent that under a lower power their cavity appeared like a red speck, were also normal and no trace of cell proliferation could be detected around them. Daunic has reported a similar case. Death occurred with great rapidity and at the autopsy large quantities of bacilli were found in all the organs, especially in the kidneys.

Miliary granulations are frequently found in the kidney. Tuffier thinks that they are an epi-phenomena of a general infection. According to Rayer they are found in the cortex, sometimes in the medullary substance. When in the cortex, they are disseminated or form whitish-gray tracts running from the periphery toward the center and following the direction of the renal vessels. Lecorché gives the same description. The granulations are localized in the neighborhood of the arteries which separate the pyramids of Farrein. Following the arteries longitudinal series or groups of tuberculous granulations are to be seen.

Topographically, the granulations predominate in the cortex, because the blood current is slow in the glomeruli and in the intertubal spaces, and for this reason the bacilli find much difficulty in their progress

forward without joining colonies in a region very favorable for their development.

Miliary granulations vary in diameter from 1 to 2 mm. Usually they are isolated, of a white or yellow color, easily dissociated and form on a cover glass small granular bodies. When in the state of small tubercles they sometimes present the aspect of a small, irregular whitish plaque. With the naked eye the surrounding parenchyma appears normal or as if a slight hyperemia were present. Microscopically, tuberculous follicles and elementary nodules with giant cells are found. The bacillus is always to be found, sometimes in great number. They are seen in groups in the interior of and around the epithelial cells. Often, however, the bacilli are few in number, one or two being found in each giant cell.

If you examine a preparation you will remark that, all about, the renal parenchyma has undergone a marked denutrition, the tubes have desquamated and their flattened epithelium shows that they are inactive. Others only show a decrease in the diameter of their canal, with sclerosis of their walls; some are even completely retracted and only contain the remains of their epithelium in the form of granular fatty debris. The glomeruli look like rosy spots and too small for their enveloping capsule. They are inactive and are only simple fibrous cicatrices. A tubercle can become fibrous in the kidney as in any other organ and is then composed of connective tissue elements in a state of hyperplasia. From the tubercle start off fine fibrous bands which extend into the surrounding parenchyma, thus binding it intimately with the tubercle.

In the case of large miliary granulations, the neighboring renal tissue is far more diseased and several granulations may be distinctly seen in one tubercle. Between the tubercles connective tissue bands alternating with embryonal cells are found while the kidney tissue has completely disappeared. The majority of these granulations are caseous. In their center a nearly homogeneous tissue made up of degenerated cells is found. These granulations are usually grouped around an artery.

This miliary tuberculosis appears during the progress of an acute infection with fever, as is so often seen in children. Usually it coincides with a tuberculosis of both kidneys and the spleen. Nevertheless, these tubercles are found in the adult during a pulmonary tuberculosis, but incidentally only, so that clinically they can hardly be taken into consideration.

To sum up it may be said that there is no constant localization for tuberculous granulations. They occupy indifferently the peri-vascular tissue, the track of a vessel, a glomerulus or a space corresponding to several renal tubes. The tuberculous tissue has the same characters in the kidneys as in any other organ. Caseification and the vitreous aspect occur early and the giant cells appear soon after. When the granulations develop in large numbers in a localized spot or in the entire kidney they rapidly run together, undergo caseous degeneration, and thus give rise to more or less extensive destruction of the renal tissues.

This leads me to the study of tuberculous cavities and infiltrating tuberculosis.

Since the writings of Bayle, Roger, Lecorché, Guyon, Reclus, Tuffier, Newman and many others, we know the surprising shape, size, etc., that a tuberculous kidney may present. We will divide this form of tuberculosis into the four following varieties, viz.:

1, nodular infiltration; 2, tuberculous pyelo-nephritis; 3, massive degeneration of the kidney; 4, tuberculous hydronephrosis.

Nodular infiltration is characterized by round masses of a yellowish-gray color, sometimes projecting above the surface of the organ. The kidney is not entirely invaded, only part of its parenchyma being the seat of disease. Sometimes the disease is seen in the form of a small tumor on the surface of the kidney, whitish-yellow in color and firm in consistency, but when caseification is about to occur it is soft to the touch. At other times the disease occurs as a large mass, deeply seated in the renal tissues, while at the surface of the organ it projects, its surface being more or less irregular. Occasionally a series of smaller confluent nodules are found, hard and white in formation, those undergoing degeneration melt in a granular mass contained in the excavations hollowed out in the parenchyma of the kidney. The nodules are consequently multiple, some being hard, some caseous.

Tuberculous pyelo-nephritis is rather more of an accident due to a peculiarity in evolution than a special form of the disease. These foci of nodular infiltration soften and break down and empty into the pelvis of the kidney. This is consequently a modification of the nodular variety, or as I might express it, the ultimate stage of nodular infiltration.

It is in these cases that the kidney is destroyed by the irregular cavities with indurated and ragged borders. From these cavities certain products are expelled which give rise to the formation of an enormous amount of pus. The kidney is filled with cavities increased in size and misshapen. It has a whitish, lardaceous aspect and when cut open exposes the numerous cavities which open into each other or communicate with the calices and pelvis of the kidney. The capsule of the organ is very adherent over these cavities and is adherent to the peritoneum and quadratus lumborum as well.

Microscopically, three zones may be distinguished: 1, an internal zone made up of the debris of caseous elements; 2, a middle zone of tuberculous infiltration having a tendency toward sclerosis; 3, an external zone composed of embryonal tissue. If you remove the caseous matter which is often very adherent to the walls of the cavities, you will remark that the walls are smooth, resistant and form true pyogenic membranes, surrounded by a fibrous tissue. The caseous matter does not contain the bacillus and is simply made up of degenerate cells.

The walls of the cavities are formed by a network of connective tissue, which varies greatly in different parts. In some places the connective tissue fibers are close together, while at others a simple mass of embryonal cells is all that can be discovered. It is a pyogenic membrane because it has embryonal cells, giant cells and numerous vessels of new formation.

These foreign and at the same time destructive elements finally reach the neighboring renal tissue, pressing upon the tubes, invading them by means of the agglomeration of embryonal cells and newly formed vessels, which are more highly organized than in the walls of the cavity but whose fragile tissues easily break down. Other parts of the renal tissue may undergo fatty degeneration of the epithelium as well as amyloid degeneration of the glomeruli.

Massive degeneration of the kidney.—In this case, the renal tissues no longer exist; they are only repre-

sented by a thin and transparent membrane which contains a solid thick mass, very similar to putty or to the contents of a dermoid cyst.

This enveloping membrane sends off branches which incompletely divide the tuberculous mass. The caseous matter is sometimes very considerable in amount and may reach such dimensions as to obliterate the ureter. The exit of pus, urine and caseous debris being no longer possible they accumulate and distend the kidney to an extreme degree.

Tuberculous hydronephrosis is the result of this compression of the ureter, and in no way differs from the aseptic dilatation of the kidney. A membrane, sending off incomplete divisions, the contents of which are a yellow transparent liquid, is all that is found. The bacillus of tuberculosis is found in this fluid when inoculated into animals.

The kidney tissue is not so diseased as in the preceding varieties, it being especially distended by obliteration of the ureteral orifice. The ureter is increased in size, its walls thickened and indurated, while its lumen is either filiform or absent.

The process of cure may stop the progress of the lesions and if it declares itself in its various ways a true calcification is seen to take place. The caseous mass becomes thicker and is transformed finally into calcareous masses.

The lesions in the neighboring tissues are perirenal tuberculous abscesses. As a primary lesion they are infrequent but secondarily they often follow a tuberculosis of the kidney. Adhesions may form between the kidney and the intestines, vena cava and other viscera.

The ureter is not always attacked but usually it is somewhat infiltrated or thickened, while the mucous membrane is exfoliated and the lumen of the canal choked with debris.

Such are the principal forms of tuberculosis of the kidney. It may occur in the form of small single, grayish, semi-transparent granulations, forming a confluent or discrete eruption in the entire organ. At other times it forms larger masses, a kind of small caseous tumor whose aspect and consistency varies according to the age of the lesion.

In the acute form, the granulations do not evolve on account of the rapid progress of the disease. In the chronic form, the disease forms large masses which may undergo caseous softening and then form real tumors of various sizes, or it may produce multiple cavities which burrow to such an extent as to render the walls transparent and transforming the kidney into a vast focus of disease.

The capsule often becomes infiltrated and the calices, pelvis and ureter are invaded by the neoplasm. They become thickened in their turn, and finally ulcerated; then they are distended and dilated by the urine which is prevented from flowing through them.

I now call your attention to experimental tuberculosis. In infectious diseases renal lesions are often found, due sometimes to bacteria, at others to the toxins that they secrete. When bacteria become localized in certain tissues they secrete poisons or toxins which, when absorbed and spread throughout the economy by the lymphatics and blood, produce changes in other parts.

As I have already pointed out, the bacillus of tuberculosis may become localized and produce lesions in the kidney. Its toxins also cause lesions of the renal epithelium, and it is this particular point on which I

wish to insist. We know the lesions due to the proliferation of this bacillus in the parenchyma of the kidney in man and this knowledge must be completed by experiments on animals.

Experimental tuberculosis of the kidney is realized as follows: *By intravenous injections*, which is not, however, a sure way of producing infection, but if it is secured it is only secondary. The granulations are not primary and demonstrate a recent dissemination of the bacillus; consequently the lungs, which act as a filter, should be avoided.

Direct inoculation of the kidney through the lumbar region has been practiced by Kostenich and Volkow, but as Borel remarks, this method has many defects. In the first place, it differs from the natural ways and it adds to the tuberculous process an intense process of repair which complicates the experiment.

Arterial injections in the carotid and aorta have been performed by Borel.

The question now comes, do the experimental facts confirm the theories established, on the pathologic anatomy of tuberculosis of the kidney? According to Virchow, the renal tubercle is made up of a lymphoid proliferation of connective tissue. The cellular elements of the gland only undergo a simple atrophy or a necrosis, but it is always the connective tissue which forms the soil in which the tubercles develop.

Baumgarten was the first to produce tuberculosis of the kidney experimentally. He injected the bacillus in the veins and studied the renal lesions which were secondary to the pulmonary tuberculosis thus produced. The first phenomenon which provokes the presence of Koch's bacillus is a karyokinesis of the fixed epithelial cells of the uriniferous tubes, of the endothelium of the capillaries and the elements of the wall of the glomeruli.

Later on, epithelioid cells are produced, and with such great rapidity in the uriniferous canals that they become completely obstructed. According to Baumgarten the proliferation of the fixed cells is the principal process of tuberculosis.

Kostenich and Volkow confirmed Baumgarten's results. They directly pricked the kidneys and three hours later found an intense polynuclear leucocythemia. Sometimes the bacilli appeared to be enclosed in the leucocytes, at others they appeared to be on the outside.

After twenty-four hours there was an intense karyokinesis in the cells of the canaliculi, while between them there appeared pale nuclei of various shapes which later resembled renal epithelial cells as well as epithelioid cells. According to these writers the latter were derived from the intercanalicular cells.

Borel obtained different results, for he never found the bacilli in the glandular tubes. From the very first, the bacilli were seized by the polynuclear leucocytes which accumulated in the dilated loops of the glomerular capillaries. Among these leucocytes irregular oval nuclei, surrounded by a granular protoplasm containing the bacilli, appeared on the third day. The nuclei and protoplasm belonged to monocellular elements. The same phenomena occurred in the intercellular tissue; these elements were distinctly different from connective tissue or endothelial cells.

The cells of the tubercle are stationary, movable elements and do not appear to result from a proliferation of pre-existing fixed, connective or endothelial cells. According to Borel, the tuberculous granulation is essentially interstitial and of lymphatic origin.

The epithelioid cells are the result of a natural evolution and development of the lymphatic cells localized in a given region of the economy. The tubercle is an accumulation of lymphatic cells.

The epithelium of the kidney plays no active part; it is only irritated by the process of atrophy or necrosis going on in the neighboring tissues. According to Baumgarten on the contrary, the karyokinesis of the fixed cells and renal epithelium is the predominating tuberculous process, while Borel claims the tuberculous granulation is a lymphatic formation, identical in all organs, which confirms Metchnikoff's theory.

The results of experiments differ consequently as to the intimate development, to the histogenesis of the primary elements, but they complete the histologic and pathologic facts that I gave in the beginning of this lecture.

They demonstrate that there is only one primary tuberculosis with a predominating glomerular or cortical localization; that there is only one granular tuberculosis scattered throughout the entire organ with a predominating perivascular localization. In both these cases the processus is always interstitial and the only active elements of the tubercle are the lymphatic tissues. The various elements of the kidney, particularly the renal epithelium, in no way enter into the formation of the tubercle.

Toxins of tuberculosis.—The study of the toxins of tuberculosis leads me to say a few words regarding tuberculous nephritis as well as amyloid degeneration of the kidney.

Bouchard, in 1881, was the first to draw attention to the infectious nephritides that accompany diphtheria, typhoid fever and tuberculosis. Later on Strauss, Cohnheim and Gaucher described the lesions found in the kidney, produced by these toxins. In 1886, Duraud-Fardel demonstrated the presence of the bacillus of tuberculosis in the kidney and Coffin described tuberculous nephritis which, according to this writer, presented the characters of an infectious nephritis besides the direct tuberculous lesions.

There are other nephritides which are apparently not tuberculous, in this sense, that the simple tuberculous nodules or masses of caseous material are absent. Now, these nephritides produced by the presence of a tuberculosis are produced by the irritation caused by the elimination of tuberculous toxins. Bartels seems to have foreseen what experimental pathology has demonstrated, and Grancher and Martin when trying to obtain an antituberculous vaccination with old cultures, observed death from nephritis eight times, and they admit that the attenuated tuberculous virus contains a toxin which causes nephritis and paraplegia. Koch's tuberculin has caused nephritis many times.

Tuberculous nephritis.—The kidney presents marked changes in size, color and weight. Rayer described parenchymatous nephritis or the so-called "large white kidney." Siedallu believes that this form of renal disease frequently occurs in tuberculosis.

According to Lancereaux, the contracted kidney of interstitial nephritis is more frequently seen in this disease. Of 281 tuberculous nephritides, Bamberger found the large white kidney 157 times, 47 times an acute nephritis and 77 times the atrophic variety.

Generally the kidney is larger than normal and appears distended from the congestion of which it is the seat. The capsule is soft and is easily decorti-

cated. The kidney is a dark bluish red, its surface being smooth and shiny.

Macroscopically the cortical substance is bluish in color as if it were undergoing fatty degeneration. The pyramids are distinctly seen, while the glomeruli are red and projecting. Microscopically two kinds of lesions are found. The first is a change in the epithelium which is only slight and during life does not produce albuminuria. In the second form albumin has been found in the urine during life and the lesions are far more extensive. Both forms are simply stages of the same processus.

Slight nephritis without albuminuria.—The glomeruli are only slightly diseased; the cells of Bowman's capsule are in proliferation. The endothelium of the vessels of the glomeruli are degenerated with minute drops of fat. Globules are present between the vesicular loops and the cavity of the capsule. In the tubuli contorti the cells are large, cloudy and swollen, while the epithelium is filled with drops of fat. The intertubular connective tissue undergoes a marked hypertrophy in tuberculous patients presenting an arterio-sclerosis.

Severe nephritis with albuminuria.—The microscopic lesions are similar to the preceding nephritis, only they are very much more marked. Degeneration of the collecting tubes is always present, while the caliber of the tubuli contorti is great, the latter are distended and tumefied, their epithelium is swollen and granular while in some parts it has secreted colloid masses which block up the lumen of the tube. Sometimes the epithelium undergoes cloudy swelling and secretes hyaline masses; the former is flattened, only forming a simple layer of cells with granular protoplasm. In the interior of the tubes are yellowish masses, sometimes having the epithelial cells detached; these are the casts.

The endothelial cells of the capsule are in active proliferation, filling the cavity with debris, while the glomeruli are in a stage of congestion, sometimes amyloid.

The description that I have given leads us to suppose that there really exists a tubercular nephritis and that it begins with the tuberculosis. This nephritis is frequent in the rabbit after vaccination with tuberculosis and has been observed by Grancher and Martin. Daunic also has seen them in his experiments.

Thus these lesions are probably due to the toxins of tuberculosis. Their frequency, their characteristic aspect, both of which are always present, is in favor of this opinion. The toxicity of the products of tuberculosis is complex, but from what I have said we may conclude that these nephritides are not always due to the presence of the bacilli in the kidney but are often due to irritation set up by the elimination of their toxins.

Amyloid degeneration.—Many diseases may give rise to this lesion and it has nothing specific about it. There is however an amyloid degeneration following tuberculosis and which has as pathognomonic cause a tuberculous infection. The kidneys present a special anatomo-pathologic aspect.

The glomeruli are semi-transparent and have a shiny waxy aspect which is characteristic. Iodin colors the glomeruli dark brown, while sulphuric acid gives them a dark violet hue.

In the beginning the lesion is almost entirely localized in the capillaries of the glomeruli, the former being thickened, but later the glomeruli are in total-

ity invaded, the lesion then being seated in the walls of the arteries. It is consequently by the vessels that the amyloid infiltration is set up. Weigert, Lecorché and others, think that the coincidence of amyloid degeneration and large white kidney (chronic diffuse subacute nephritis) is generally the rule, and that the amyloid infiltration is always an accessory lesion put into action by a former nephritis.

Although a vast amount has been written regarding this form of degeneration, we are as yet not quite sure to what factor it should be attributed. It was thought that a particular substance formed in abscesses, ulcers, tuberculous cavities, etc., resulting from the oxidizing action of the air on pus. This substance was considered a chemic poison produced by the influence of fermentation and was easily produced experimentally in animals by inoculating other toxins than those found in tuberculosis.

Thus it was that Charrin and Bouchard, by intoxicating an animal with blue pus and filtered cultures of the pyocyanic bacillus, produced amyloid degeneration in the breast and kidneys. The same results were obtained with tuberculosis.

We can thus suppose there is not direct action of the bacteria on the walls of the vessels. Perhaps amyloid degeneration is due to the toxins of tuberculosis in the pus, and the tubercles in different organs are surrounded by a thick layer of connective tissue which always undergoes amyloid degeneration.

I now come to the etiology and pathogenesis of tuberculosis of the kidney, which disease occurs at all ages but is more common in children and old people. Women are more prone to this disease than men. Of forty-three cases seen by Tuffier, twenty-nine were women and fourteen males. Vigneron published statistics of 133 operations for this renal complication, ninety-seven were performed on women and only thirty-six on men.

According to Roberts, the disease is more frequent between the ages of 30 and 40 years, while for Rosenstein it is more common between 15 and 30. Personally, I think that it occurs more frequently between 20 and 35, but Tapret reports a case of the affection in a man aged 97 and Glück removed a tuberculous kidney from a child of 3½ years.

The kidney is very rarely attacked by tuberculosis and Louis only found 5 cases out of 170 autopsies. Of 1317 patients dying from tuberculosis at the hospital at Prague there were 75 tuberculous kidneys. In children, according to Rilliet and Barthez, out of seventy-two autopsies, forty-nine cases of renal tuberculosis were found.

Generally speaking, renal tuberculosis is under the dependence of many influences produced by the general infection, and here as in other affections, we must take into consideration denutrition, contagion, heredity, etc.

The kidney like the lung is under the control of these various etiologic factors, which if they do not directly produce the lesion, admirably prepare the organ for the disease.

The starting point of tuberculosis of the urinary system has been the subject of much discussion. The pathologic anatomy that I have given, demonstrates that the infectious process is produced by Koch's bacillus. Now, the question is: Does the affection begin in the prostate and seminal vesicles, the bacilli attacking the kidney and bladder afterward; or is the bladder the first to be diseased, or is it the kidney?

Each organ of the genito-urinary system has in turn been supposed to be the primary seat of the infection and all ways of propagation have been admitted as possible. There are two principal theories, however: the first is that the tubercle forms in the testicle and epididymis, from whence it invades the other organs; while the second is that the infection begins in the kidney and from there attacks the other parts of the excretory system. Both are upheld, but if you closely observe the cases reported it will appear clearly that the disease commences in the kidney, and from this organ it penetrates the urinary tract, invading successively the ureters, bladder, the posterior urethra, the prostate, seminal vesicles, the vas deferens, epididymis and testicle.

If you find at an autopsy a renal tuberculosis of recent date, by that I mean miliary granulations, one is extremely sure to find the lesion farther down in the urinary system. Lecorché and Roger have especially found lesions entirely limited in the kidney; the secondary tubercles were only in the kidney, rarely did they find them in the pelvis or calices and still more infrequently in the ureters and bladder.

Le Dentu says that tuberculosis localized in the kidney is very infrequent, at least it is rarely reported. Now this local tuberculosis, which is a mortal danger, becomes generalized because from the kidney the bacilli infect the economy, causing a general infection. For a while this lesion, which is only in the kidney, remains local, but soon it invades the system and for this reason a renal tuberculosis is rarely met with at the autopsy. Consequently, Le Dentu admits that localized renal tuberculosis is theoretically explained.

This being admitted, we know that Cayla claims that genito-urinary tuberculosis follows the urinary tract downward; starting from the kidney it first invades the urinary, then the genital system.

Now contrary to Cayla, most writers believe in an ascending infection and it would appear that clinical facts of tuberculous infection, contracted during coitus, would plead in favor of this hypothesis. And do we not see and follow for many years patients with a tubercular prostate or testicle, who never have symptoms of a renal infection?

According to Hallé, the disease begins sometimes in the lower genital or urinary organs, the prostate or posterior urethra, afterward invading the bladder and kidneys, thus appearing to be an ascending infection of external origin. But this ascending infection is far from being in accord with the histories of most of the cases reported.

Often it is the bladder or the kidneys which are the primary seat of the affection, and other localizations of the disease are only secondary symptoms of a general tuberculous infection.

Daunic does not admit that the bacillus can penetrate into the kidney from coitus, and gives the following reasons, based on the practice of a number of eminent surgeons: Tuberculosis of the uterus is very rare, consequently the male can only be contaminated infrequently. Hillairet and Looten both report a case of tuberculosis of the glans penis, but in both cases the diagnosis was not absolute. Never before has a case of inoculated tuberculosis been reported on the penis, glans or anterior part of the urethra.

The seat of tuberculous lesions in the female genital organs does not seem to be that of one resulting from coitus; if this were the case, the tubercles would first occur in the vagina and cervix, which in reality

is very rare. The bacilli are, consequently, brought by the blood, as is proved by pathologic anatomy when it shows that the bacilli are more often found in the glomeruli, arteries of the kidney and in their walls, and also that the tuberculous granulations are either in the interior or neighborhood of the vessels. Consequently, according to Daunic, a renal, secondary to a genito-urinary tuberculosis, is as yet unexplained as regards its pathogenesis. The bacillus can penetrate the kidney by the blood and by the ureters from below upward, but what appears to be settled, is that the bacillus can not infect the kidney from coitus.

Besides a genito-urinary tuberculosis, there is another form which is diffuse, being pleural, pulmonary, genital, peritoneal, etc. In this case, we have what is termed "the medical tuberculous kidney." This term should not be employed in its exact meaning, for according to the indications, prognosis and progress of the lesions, a medical tuberculous kidney may become surgical.

In this case, in the pathologic point of view, the kidney may have had a primary focus of tuberculosis from which the bacilli penetrate the entire economy through the blood.

But the kidney may only be a secondary focus depending on lesions in the lungs, from which point the bacilli attain the kidney and become localized there, producing a lesion secondary to that in the lungs.

In the first case, we have a local primary tuberculosis of the kidney, producing a general infection; in the second, the primary lesion is in an organ other than the kidney and the latter is infected secondarily; consequently, tuberculosis of the kidney presents two different pathologic conditions, viz., primary and secondary infections.

As to its starting point the majority of reported cases seem to show that the seminal vesicles and prostate with secondary infection of the bladder and kidney is the more frequent manner of infection. Tuberculosis of the kidney *ab coitu* should be rejected as impossible, for the kidney only may be the primary seat of the process and this localized primary tuberculosis of the kidney can progressively infect the ureters and genito-urinary system.

Regarding the way in which the kidney is attacked by tuberculosis, Wesens believes that the bacilli are more frequently present in chronic tuberculosis than in the acute form. Now we know, according to Cornil, Baumgarten and others, that it is precisely in the military form, in acute attacks, that the specific organism of the affection is found. Baumgarten found the bacillus in the tubuli contorti and believes that they come from the neighboring capillaries. Durand-Fardel saw them in the glomeruli and interior of the renal vessels. Consequently the transportation of the bacilli is accomplished by the arterial circulation.

Probably the organism invades the glomeruli and also the various parts of the cortical substance. The tubercle extends in size from its periphery, and in this extension the cells of the tubuli contorti play the most important part. The bacillus imitates the cells; the nuclei of the epithelium presents karyokinetic forms; new cells form and accumulate, while the walls of the tubuli contorti give way to this pressure. The neighboring granulations melt together and soon after the epithelioid cells take on the aspect of embryonal elements.

Brault gives the following description: When a uriniferous tube is invaded by the bacilli the cells, after a short irritation, become swollen, caseous, and form a protoplasmic mass, in the center of which Koch's organism is sometimes found.

More often, however, fine granulations in which the lymphatic cells are predominant, fill the inter-tubular spaces and contain giant cells.

Large tubercles often succeed the elementary ones and it may be admitted that the former arise from microbic emboli. The distribution of these emboli is irregular, as they occur in any part of the kidney and genito-urinary system.

To sum up, we have a primary tuberculosis of the kidney in patients who have never presented any other symptom of bacillosis, the starting point being in the kidney or bladder. The infection occurs by the blood. From the cortex the processus invades the medullary substance, the pelvis of the kidney, ureter and bladder.

The secondary form occurs in subjects presenting tuberculous lesions in full evolution, the primary focus being in the lungs, joints, lymphatic glands, or one of the genital organs of man. The primary lesion is often in the bladder, the lesion of the kidney taking place by ascending infection. In some cases there may be a secondary renal tuberculosis, terminating with a secondary descending tuberculosis of the urinary organs.

(To be continued.)

DISEASES OF THE CONJUNCTIVA IN RELATION TO DISEASES OF THE NASAL PASSAGES.

Presented to the Section on Laryngology and Otology at the Forty-eighth Annual Meeting of the American Medical Association,
at Philadelphia, Pa., June, 1-4, 1897.

BY ROBERT N. KEELY, M.D.

PHILADELPHIA, PA.

It is only recently that the relation of cause and effect which exists between nasal affections and those of the conjunctiva have begun to attract attention. That this relation does exist there can be no doubt, but it has not been properly appreciated.

The obstinate and unsatisfactory course which many cases of conjunctivitis pursue is well known; it usually means a long period of suffering and disability to the patient and a wearisome, unresponsive and unsatisfactory treatment on the part of the physician. The practical discovery of the dependence of conjunctival disease on that of the nasal cavities is due perhaps more to the nasal than to the ophthalmic surgeon. This was due not so much to the lack of ability on the part of the oculist as to the immense advances recently made in the domain of nasal surgery. Previous to these, although it was known that the nasal mucous membrane as well as the ocular was affected, still the means of treatment were practically restricted to the former. Until the last decade physicians, as a rule, had comparatively little knowledge as to the treatment of the nasal portion of the diseased tract. In fact so little was known that any existing departure of the nasal cavity from a state of health could not be recognized or diagnosticated. It was not known what constituted health and what disease. As, however, the nasal surgeons began to recognize and master nasal diseases it was found that in so doing they often encountered cases in which an accompanying ocular

inflammation cleared up without any special treatment having been directed to it. This served to attract attention to the causal relation existing between the two affections; also the ophthalmic surgeon seeing the advances made by his nasal colleague, and his success in the treatment of the hitherto rebellious nasal troubles, sought his aid more frequently, particularly in affections of the lachrymal duct and sac where the connection of the two affections were most serious and most evident.

It had long been known that conjunctivitis was often dependent on diseases of the lachrymal duct and sac, and when these had been shown to be often dependent on trouble within the nose, it followed as a matter of course that conjunctivitis could likewise be due to extension of the inflammation from the nasal cavity.

The inquiry once having been raised, the advanced state of nasal surgery was able at once to solve the questions presented by the oculist. It was found that the nasal mucous membrane was a most sensitive structure and rapidly responded to and resented all forms of irritation. Inflammatory evidences in the conjunctiva were preceded by sneezing and swelling of the Schneiderian membrane in acute cases and the nasal symptoms preceded the ocular ones. In chronic cases it was found that the turbinated tissues were hypertrophied, that cartilaginous and bony spurs impeded the free passage of air; that deviations of the septum also acted as an obstruction, and tended to the accumulation of mucus and favored the establishment and aggravation of catarrhal troubles. The proof, however, of the causative action of nasal affections on ocular ones was the disappearance of the latter on the removal or cure of the former. The whole question is one of such recent date that notwithstanding its satisfactory solution, it has not received the attention of ophthalmic surgeons that it deserves.

In our text-books particularly, the references to nasal trouble as a causative factor in conjunctivitis is not sufficiently insisted on nor its action explained. Neither are sufficient details of treatment given to enable the practitioner to relieve those cases of conjunctivitis which can only be cured by properly remedying the coexisting nasal affection on which it depends. It is not to be expected of the oculist that he shall undertake the sole treatment of the nasal troubles, but he should have such a knowledge as will enable him to properly examine and recognize abnormal conditions, and even if circumstances require, to conduct the treatment of the milder forms. In many cases the treatment must be carried out in conjunction with a colleague skilled in nasal surgery, and this will often prove the most efficacious and desirable plan.

The following cases may serve to show the association of nasal and ocular troubles:

A man aged 36 years had a violent inflammation of the left eye associated with discharge from the nostril. The eye was swollen almost shut, and the examination showed the mucous surface of the lids covered with a layer of false membrane which was easily stripped off. The right eye was not affected. The patient had had a traumatic deviation of the nasal septum for which he had been operated on two years previously. While considerable breathing space had been obtained, an ulcerated surface had persisted ever since. He had suffered for three or four years from slight attacks of hay asthma. These followed the injury to the nose

and existed previous to the operation. The discharge from the nostril was thick and tenacious and excoriated the lip.

A false membrane covered the entire nasal mucosa and extended down into the naso-pharynx. Dr. Kyle examined the membrane bacteriologically but failed to find any Klebs-Loeffler bacilli, only streptococci and staphylococci. It was supposed the disease was a streptococcus infection, and that the eye had become secondarily involved through the medium of the nasal duct. The nostril was carefully cleansed with an antiseptic saline solution, and the ulcerated surface touched with toulol and sesquichlorid of iron of six parts to a hundred of water. The eye was washed with a boric acid solution and the nostril thoroughly cleansed every two hours with biborate and bicarbonate of soda, carbolic acid and cinnamon water and glycerin and water. There was a slight re-formation of the membrane in the eye, but none in the nostril except about the points of ulceration of the septum. The condition cleared in forty-eight hours, a mild attack of hay asthma persisted, however, for several weeks.

Another case was that of a girl aged 16 years. She suffered from a flow of tears from the right eye. She took cold easily and then the right nostril would suddenly close and a flow from the eye would begin and continue until breathing was re-established. Examination of the nose showed enormous thickening of the mucous membrane of the middle turbinate. This swollen membrane occluded the nasal duct by pressure. The condition had existed for three or four years. The duct had been probed from above and several eye washes had been used. A portion of the middle turbinate was removed together with the thickened tissue, and although a year and a half has elapsed since the operation there has been no return of the former symptoms.

The last case is one of a child aged 3 years. Both eyes were affected; the lids were red and granular and discharging a fetid pus. There was also a purulent rhinitis. Under an anti-strumous treatment of syrupus ferri iodi and the hypophosphites with a 0.0027 gram of the double sulphid of arsenic and a local application of boric acid, the eyes cleared up promptly.

1823 Vine Street.

REPORT OF A CASE OF MALIGNANT GROWTH IN THE LARYNX: TOTAL EXTIRPATION, SOLIS-COHEN METHOD.

Presented to the Section on Laryngology and Otology at the Forty-Eighth Annual Meeting of the American Medical Association at Philadelphia, June 1-4, 1897.

BY ROBERT C. MYLES, M.D.

NEW YORK, N. Y.

James Eckersley, age 49, machinist, worker in the emery room of a sewing machine factory, was sent to me Aug. 7, 1896, for diagnosis and opinion concerning the condition of his throat. He complained of loss of voice, sore throat, sore chest, cough, difficulty in breathing, poor appetite, weakness and night sweats. The cough had troubled him from time to time, for thirteen years. He was able to sing up to three months since; then he became hoarse, and has remained so up to date. I found a large growth in the larynx, which was attached to the right vocal chord and the adjacent anterior and inferior parts, and extended

across the anterior commissure. The larynx was dilated to an extreme degree by the formation. There was a small opening in the respiratory space between the arytenoids, and there were two abrasions on the top of the tumor, apparently caused by forceps in an attempt to obtain specimens for microscopic examination. I reported that the characteristics were those of malignancy, and that I would advise the removal of a deep section of the growth for microscopic examination. This was accomplished with Krause's double curette, it being the opinion of the writer that Mackenzie's cutting and Schroetter's tube forceps are not

Specimen, carcinoma of the larynx.

reliable in making deep sections of laryngeal growths. I also advised that an immediate operation of total extirpation should be performed in the event that the diagnosis was corroborated and confirmed. Dr. Vissman made a microscopic examination and reported that the tumor was a carcinoma. I advocated the Solis-Cohen operation. This was performed by Dr.

Specimen, total extirpation of carcinoma of the larynx.

J. A. Bodine Aug. 17, 1896, preliminary tracheotomy having been performed several days previously. After the patient had been anesthetized an incision was made in the median line from the hyoid bone down to the tracheotomy wound; no cross incision was made. The parts were dissected on either side from the thyroid and cricoid cartilages. The bleeding was slight, and was stopped by compression or ligature; chloroform narcosis was continued through the tracheotomy tube. The trachea was cut through at the point of junction with the cricoid, and was pulled

outward and downward, great care being taken to prevent the blood from entering through the severed end. Then the larynx was lifted upward and dissected from the esophagus, constrictor muscles, crico-arytenoid folds and the epiglottis. The esophageal and epiglottic surfaces were brought together firmly with catgut. The external excision was closed with sutures down to the lower part. The end of the trachea was stitched to the skin above the supra-sternal notch and also on the sides. The patient was fed by mouth for a few days, when the catgut gave way and allowed the milk from the pharynx to enter the wound. He was fed by a tube through the mouth after this for a time. The patient improved gradually: but at times he had attacks of profound nervous depression, with expressions of great fear of suffocation, and an indisposition to take food. The trachea receded and dragged the skin inward and became quite narrow. This was kept open by different forms of tubes: the Simrock nasal speculum was the most feasible. The tracheal walls became dry and abraded, and the patient suffered much from mucous and bloody crusts. A spray of liquid alboline with carbolic acid and eucalyptol gave him great relief. The opening became so tight that it was necessary to excise a part of the tissue where the skin and trachea unite. The communication between the wound and the pharynx gradually closed. Within a few days it was noticed that he could whisper certain words. His speech has made gradual and favorable progress. It would seem that his method of voice production is not exactly like that of Solis-Cohen's famous case. His patient had a pocket in the upper esophageal region and emitted regular puffs of air as is done in ordinary laryngeal speaking. In this case the voice seems to be produced mainly from the air being forced, by pressure of the muscles over the roughened edges of the glosso-pharyngeal region, and in this way producing enough vibration for whispered speech to be made by the tongue, lips, teeth and palate. I can not detect the slightest symptom of recurrence of the growth. He has gained rapidly in weight. The epiglottis has rather a normal appearance and position.

46 W. 38th Street.

DISCUSSION.

Dr. J. SOLIS-COHEN My case was operated on six years ago, and was doing well last year. He had a very large external growth, and I had to remove much of the skin with it. I believe that this is the ideal operation for the removal of these growths. Tracheotomy should be done ten or twelve days in advance, enabling the patient to become accustomed to breathing through the neck. This affords time for certain adhesions between the trachea and the skin, and this process, anchoring the trachea, renders the laryngectomy easier. Some few months ago, in reading a report of the Laryngological Association of Great Britain, I was impressed with the large number of successful cases presented at one meeting. I learned that most of these had been performed under chloroform and I think that is the best anesthetic in such operations. With ether there is more or less bronchial irritation and also vomiting after operation, and much of this can be obviated by the use of chloroform.

In my case I concluded that the voice was produced by the horizontal fibers of the inferior constrictor muscle of the pharynx. That patient learned to distend the sac by half swallowing the air, and if this man will learn to do the same, he will probably be able to produce a phonal sound, instead of the labial one. My case seems an example of the old idea that function precedes structure. Here was a man whose larynx had been removed, and who wanted to talk, and in the effort to talk organs connected with a different function were forced into use to accomplish the result. My patient is not able to do hard manual work, for he can not close his glottis, and an expiratory current of air can not get the leverage necessary for hard work. In the act of defecation it is necessary to close the glottis. He

was obliged at one time to occlude the orifice externally, so that this act could be performed easily.

I used no dressing or packing, and I studied the patient to see whether in swallowing there is an actual dilatation of the esophagus or whether it is simply opened like a bag and the food pushed downward. Before the wound closed we were able to see that in swallowing, the esophagus did not dilate to receive the food. My patient does not wear a tracheotomy tube. He wore one for some time, but happened to forget it one day, and finding that he did not need it, has dispensed with its use.

Dr. MACKENZIE—In the debate on malignant disease of the larynx at the Baltimore meeting of the American Laryngological Association, in 1890, I stood alone among my fellow-laryngologists, as I stand alone today, in advocacy of radical operation and by radical operation I mean total extirpation of the larynx with its lymphatics and lymphatic glands, as the only rational method of dealing with this too often fatal malady. Extirpation of the larynx was then, as it is now, denounced as an unjustifiable and ghastly procedure, and we are told that the operation should be abandoned because in malignant disease it has resulted in failure and that life has been shortened thereby. Even if this doubtful assertion be true, better a shorter life of comparative comfort than a prolonged life of hopeless agony. We are, however, dealing not with the past of this operation, but with its future. To the modern surgeon they are sufficiently apparent, but I believe there is one thing that the records of the future will show, namely, the reason so many cases have terminated in failure and death is because the disease has not been radically dealt with. As long as we have lymphatics to carry infection and glands to become infected, so long will our patient be subjected to ultimate danger. The more I investigate the subject and the more I see of the treatment of cancer in general, the more convinced I become that there is only one rational method of dealing with cancer of the larynx. Early total extirpation of the organ with its tributary lymphatics and glands, whether the latter be apparently diseased or not, is the only possible safeguard against recurrence or metastasis. By no other method can we give the patient a reasonable assurance of a permanent lease on life. The surgeon who is abreast of the times does not trifle with cancer in other organs. Why should the larynx be made the exception to the rule? We will have to learn the same lesson here that we are slowly learning in the case of cancer in other parts of the body. No one at the present day thinks of taking out half a breast, half a uterus, or half a kidney for cancer, no matter how circumscribed the growth may be. It is impossible by inspection either with the laryngoscope or after preliminary division of the thyroid, by transillumination or by the sense of touch, to limit the extent of the disease before operation. As I have demonstrated, even after removal of the larynx the disease may be apparent in one side of the organ and not in the other, and yet the microscope show extensive cancerous deposit in the seemingly normal side. This condition is liable to occur in cases in which the epithelioma originates in the deep-seated glands and may not approach the surface until a late stage of the disease. It is also possible that in a more or less advanced stage of cancer of the larynx or even in its early history we may find young cells in the neighboring lymphatics, as Halsted has demonstrated in the case of cancer of the breast. In the presence, therefore, of the fact that it is impossible to limit the disease by inspection and the sense of touch and in the light of the revelations of the microscope it becomes a serious question whether we accomplish any lasting good by any operation short of complete excision of the larynx and the neighboring lymphatics and glands. Certainly if the disease approaches the middle line, the imperative necessity of complete removal must be apparent to the most timid and doubting operator. Confronted by this uncertainty, the position of the surgeon is a most responsible one. Operations of this class should only be undertaken by surgeons of acknowledged skill and experience and with a conscientious recognition of the ethical relations of operator and patient. Thyrotomy with partial removal of the larynx is not up to date surgery, and is a reversion to and resurrection of a method of procedure that was discredited and abandoned half a century ago.

Beside the question of life-saving, all other considerations pale into insignificance. Given a cancer confined to the larynx (even though the entire interior of that organ be involved) in a person in fairly good condition, and offering no absolute contra-indication to operation, I would no more hesitate to recommend excision of the larynx and lymphatics than I would under similar circumstances hesitate to recommend excision of the breast. The conditions surrounding the two operations may be dissimilar and the danger greater in the one than in the other, but to the patient it is the choice between danger and death.

A great deal has been said in recent years about the dangers of thyrotomy and we are told that we must not operate if the lymphatic glands of the neck be involved. The so called dangers of thyrotomy are largely fanciful. If there be any chance of saving life, I believe a preliminary thyrotomy justifiable, even in the presence of external glandular enlargement, provided such involvement be not, on its face, too extensive. More than that, if, on thorough exposure of the parts—assuming that there be no serious contra-indication to operation—it be found that the disease can be thoroughly eradicated, even if such eradication should involve more or less deep dissection of the tissues of the neck, it is far better to give the patient that chance of life than to allow him to drift on to certain and possible death.

Dr. RICHARDSON The extirpation of a larynx containing a growth which has been proved microscopically to be carcinomatous is as justifiable an operation as can be done in the range of surgery. The operation should be done early. It is impossible, from a laryngoscopic examination, to judge of the extent and character of the growth. We get such a foreshortened image that nothing can be ascertained except perhaps the fact of the malignancy of the growth. Operations short of total extirpation are worse than useless. Where tissue of a malignant nature still exists it is sure to lead to a fatal termination of the case. The radical operation is one which can be executed with considerable ease, and can be made almost a bloodless procedure unless some of the veins are severed; and is not attended with any marked degree of shock. The danger and difficulty lie in the post-operative stage, until the wound is healed. It is during this period that most of the cases succumb.

Dr. Cohen's plan of doing the preliminary tracheotomy ten or twelve days in advance is well advised. The tendency with many is to do the extirpation too soon after the tracheotomy. I fear that this was one of the causes of the fatal issue in my case, for I only waited a week, when two would have been better. However, I was forced to go on because of the weakened condition of my patient.

Dr. SWEENEY—I would like to question Dr. Myles in reference to the influence on the nasal secretions.

Dr. MYLES—They seem to be in very good condition.

Dr. BRYAN—It seems to me that the patient swallows air and the voice is produced by a vibratory expulsion.

Dr. MAKUEN—Though this man can only whisper, I believe that this whisper is due to the action of the organs of articulation upon the natural column of air. It is clear to my mind that a whisper is not dependent upon the larynx or upon the vocal chords. There are no vibrating surfaces here as in Dr. Cohen's case.

Dr. GIBBONS—Four years ago I registered the voice of Dr. Cohen's patient on the phonographic cylinder, and a year and a half ago I registered it again and found great improvement. Such a test should be made every six months.

Dr. MYLES—These cases should be seen promptly by men competent to examine them, and should then be taken to a general surgeon for operation. I prefer a surgeon in most cases, because the operation does not occur frequently enough to keep the laryngologist's hand active, though I should not hesitate to do it myself if necessary.

REPORT OF TWO CASES OF SUPPURATING MASTOIDITIS.

Presented to the Section on Laryngology and Otology at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY J. H. BRYAN, M.D.

WASHINGTON, D. C.

In presenting the following cases of mastoid disease, it is with the object of demonstrating the evil results that are liable to follow acute suppurations of the middle ear, especially when treated with the indiscriminate application of poultices, and the injudicious use of the Politzer air bag. In spite of the advances that have been made within recent years in the treatment of these affections, and the serious results that are almost sure to follow when these cases are badly treated, we still find physicians using the poultice to cause an abscess of the mastoid region to break externally. It has been my misfortune to have had several of these badly managed cases to treat,

the histories of two of which are herewith subjoined. I think they are good object lessons and may be a warning to some physicians not to allow their cases to go to the verge of dissolution before operative interference.

Case 1. Acute suppurating otitis media, suppurating mastoiditis, abscess extending into the deeper tissues of the neck. T. M., white, age 56, was admitted to the Garfield hospital, June 24, 1896, stating that about six weeks previously he was suddenly seized with a severe pain in the left ear. He was treated with hot oil applications and poultices and the abscess discharged through the external auditory canal, giving him only slight relief however. The hot applications were continued notwithstanding a large swelling had formed back of the ear, which was excruciatingly painful.

On admission the patient was very much emaciated and weak. His mental faculties were decidedly obtunded, consequently it was not possible to obtain a clear history of his condition, from him. Temperature 100 degrees; pulse 60. There was a profuse discharge of pus from the external auditory canal, and a large swelling back of the ear, over the mastoid, extending upward toward the temporal region and down into the neck. Slight pressure over the swelling was very painful and caused the pus to flow more freely from the external auditory canal.

The patient was freely stimulated with whisky and strychnia and the mastoid region shaved and prepared for operation, which was performed June 25, under ether anesthesia. His condition was not considered favorable for anesthesia, but after the use of stimulants he bore that and the operation well. An incision was made commencing just above the auricle and extending down upon the neck about two and a half inches. This was followed by a discharge of a large quantity of pus, which was found to have burrowed into the deeper tissues of the neck. The cortex of the lower portion of the mastoid was completely destroyed, while the upper portion still remained firm. This was removed with the chisel and rongeur, and the antrum opened; all carious bone was removed with a sharp spoon, and in doing so the lateral sinus was exposed in nearly its full extent. As it was soft to the touch and no evidence of any septic infection, it was not opened. The sloughing tissue in the neck was scraped away with a sharp spoon, and after thoroughly irrigating the wound it was packed with iodoform gauze, and closed with a bandage; 8 P. M. temperature 101 degrees, pulse 120. Owing to the extremely weak condition of the patient he was freely stimulated with whisky.

June 26, 8 A. M. temperature was 98.4 degrees, pulse 96; 8 P. M. temperature 100 degrees, pulse 96, and stronger. Otherwise doing well.

June 27, 8 A. M. temperature 98.4 degrees, pulse 84. The wound was dressed, owing to the dressings being quite moist. In the neck wound there was still considerable sloughing tissue, which was removed. A continuous flow of pus was still observed coming from the external auditory canal.

June 30, temperature and pulse normal. Condition of the mastoid and neck wound very much improved. Large pieces of sloughing tissue removed from the lower portion of the wound. Pus continues to discharge freely through the external auditory canal, although little is observed in the mastoid antrum. The solutions pass freely from the antrum through the external auditory canal. The wound was dressed every other day on account of the free discharge of pus.

July 15, while the general condition of the patient has improved very much as well as that of the wound, pus still continues to flow through the external auditory canal. The patient was placed under ether, and the roof and posterior wall of the auditory canal were found to be in a state of extensive caries. The auricle was freed from its bony attachments and thrown forward, and the carious superior and posterior walls of the auditory canal removed with a sharp spoon. The auricle was then brought back into position and after irrigating the wound it was packed with iodoform gauze, both through the canal and from without. There was a rise of temperature to 99.8 degrees after this operation, but it fell to normal in a few days.

The general condition of the patient continued to improve, with the exception of a marked cerebral irritation amounting at times to decided delirium. This lasted about a week or ten days and then ceased.

September 30, the patient was discharged from the hospital, cured, the wound having closed completely, and with a hearing distance of one inch for the watch.

Case 2.—Acute suppurating otitis media, suppurating mastoiditis with a commencing infiltration into the neck.

The patient, a young man 19 years of age, consulted me

Jan. 11, 1897, giving the following history: December 14 he was seized with a severe pain in the left ear following a slight attack of influenza. In a few hours there was a profuse purulent discharge from the auditory canal which gave him temporary relief, the pain returning, however, with increased severity and extending over the temporal and mastoid regions. Poultices were applied and the air douches used. In a few days a swelling appeared back of the ear, which became intensely painful on pressure. This form of treatment was continued until I saw him January 11.

His condition then was serious, he being exceedingly weak and emaciated. His temperature was 99 degrees.

On examination, a profuse purulent discharge was observed flowing from the external auditory meatus, but owing to the swelling of the canal no view of the membrana tympani could be obtained. The auricle stood out prominently from the side of the head, and back of it over the mastoid region there was a large swelling extending into the neck. The parts were red and very sensitive, pitting on pressure. The patient was sent to the Garfield hospital and prepared for operation, which was performed on the following day. The incision was made commencing just above the auricle, continued over the mastoid and terminating about two inches below the apex in the neck. Pus in large quantities was found at the apex of the mastoid, burrowing into the deeper tissues of the neck, but none was found over the upper portion of the process, the tissues being swollen from edematous infiltrations. After elevating the periosteum the cortex of the process was observed to be firm, and no opening communicating with upper cells or antrum could be found, but a probe passed readily through the large cell found on the under surface of the mastoid apex. The antrum was opened and the cortex removed with a chisel, when the cells of the mastoid were found to be in a state of caries, and the pus instead of breaking through the cortex found its exit into the tissues of the neck through the under surface of the apex where there is a large cell with very thin walls usually found.

After all the diseased tissue was removed with a sharp spoon, the wound was irrigated with a solution of bichlorid of mercury (1 to 3000), packed with iodoform gauze and closed with a bandage.

January 13, the patient is free from pain and feels generally comfortable. At 8 A. M. temperature 99.2 degrees; 4 P. M. 100 degrees.

The wound was dressed on the fourth day and very little secretion observed. The temperature was now normal and remained so during the convalescence of the patient. The subsequent dressings were made every third day; the wound continuing to heal rapidly, he was able to leave the hospital, cured, March 1, with a hearing distance of five inches for the watch.

While such cases as the above are not unusual in the experience of most aural surgeons, still they are of value in demonstrating to what extreme conditions patients suffering from suppurative inflammations of the middle ear may arrive, especially when over treated with the ever popular poultice, and subjected to the injudicious use of the Politzer air bag, a most valuable instrument when properly employed, but one capable of doing great injury in the hands of the inexperienced, especially when employed in cases of children with hypertrophy of the post-nasal lymphoid tissue.

AN HISTORICAL SKETCH OF THE OPERATIONS UPON THE MASTOID PROCESS.

Presented to the Section on Laryngology and Otology at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, June 1-4, 1897.

BY LAURENCE TURNBULL, M.D., PH.D.

AURAL SURGEON JEFFERSON MEDICAL COLLEGE HOSPITAL.
PHILADELPHIA.

It is now 105 years since a Danish surgeon, Berger of Copenhagen, was suffering from non-suppurative inflammation of the tympanum attended with distressing tinnitus aurium and deafness. To relieve this

condition the operation of perforating the mastoid process was performed. The patient being old and the bones very hard, the injection used would not pass through the opening in the mastoid into the middle ear. Pain, fever, sleeplessness, vomiting and delirium closed the scene and he died eleven days after the operation. The postmortem revealed "suppurative meningitis." Where the bone had been opened it was found to be two lines in thickness, while the perforator had entered much deeper.

A regimental surgeon by the name of Jasser, in 1776, performed the same operation upon the mastoid of a soldier who had suffered for a long period from a chronic middle-ear suppuration, with occasional subacute attacks attended by great pain. The region over the mastoid was swollen and the patient was half insane with pain. Jasser made an incision over the mastoid about an inch long and found a drop of pus. Encouraged by this he cut down upon the whole length of the mastoid bone. He found the surface roughened. He passed a probe quite deeply into the mastoid cells and injected fluid into the opening; it came out of the external auditory meatus, and at the same time a large quantity of pus was discharged from the external meatus. The patient immediately exclaimed that the pain had left his ear. He fell asleep and rested uninterruptedly for ten hours. In three weeks the opening behind the ear had healed, the discharge from the auditory canal had ceased and the patient heard better than before. Stimulated by this, Jasser performed the same operation upon the other ear of the same person, from which there was no discharge, but in which the hearing was impaired. The hearing is said to have also been improved after the operation, but this is very doubtful. There was no caries of the bone.

The operation received its name from "Jasser." The indications were correct in the first case, but were wanting in the second.

This valuable surgical operation lay dormant for over fifty years by this mistake.

Von Troeltsch, in 1861, published a valuable paper in *Virchow's Archiv* upon this subject of perforation of the mastoid, resurrecting and describing the operation in a clear and satisfactory manner. He then reported a case in which he had, in 1858, perforated the mastoid process with a blunt probe. According to Troeltsch's own words, although the indications that opening of the mastoid to remove dead bone and concealed pus and thus secure drainage, were now considered imperative and clear, he opened the softened mastoid with fear and trembling. He says: "I went to work with uncommon care, even with dread." The case was a success.

I now quote my own case, the report of which follows as given by Dr. D. B. St. John Roosa of New York (extract from *Philadelphia Medical and Surgical Reporter*, Vol. vii, p. 463, February, 1862) and published by him in a history of the operation, to be found in his work on "Diseases of the Ear" (1891, p. 540).

"In February, 1862, Laurence Turnbull, M.D., published two cases in which he made an incision down to the bone, and a third in which two months after he had opened the external tissues, he perforated the surface of the bone with a sharp hollow probe and applied nitrate of silver freely. A month later he again broke down part of the bone and nineteen days later he removed a large piece which was found to be

movable with a probe. This was an operation similar to that of Troeltsch, although the German surgeon waited only a few days before venturing to perforate the cells with a probe, while the American delayed for two months. In spite of its exclusion from some tables, Turnbull's cases belong to the same category with that of the reviver of the operation." It was operated upon but three years after Troeltsch's case, and only one year after it was published. This lad, now a man of 34, made a perfect recovery and is still well and living.

In confirmation of the above facts, Professor Gruber, in his text-book "Diseases of the Ear" (Translation by Drs. Edward Law and Coleman Jewell, London, 1893, p. 462) states that, "in more recent times the attention of aural surgeons was again turned to this operative measure by Von Troeltsch, who gave as indications for its performance: Otitis media with collection of pus in the mastoid cells, which, even with coexistent perforation of the drum membrane, can not otherwise be evacuated, and the symptoms are too urgent to justify waiting for spontaneous opening of the abscess." The operation has been performed on these grounds with more or less good results by Von Troeltsch,¹ Turnbull,² Pagenstecher,³ Follin,⁴ Schwartze,⁵ Gruber,⁶ Mayer,⁷ Jacoby⁸ and others. The operation first came into more extensive use, however, in consequence of Schwartze's⁹ zealous advocacy.

In the table published by Schwartze and Eysell they give the writer credit for his operation in 1862.

The indications given by Schwartze for performing the mastoid process are:

1. Acute inflammation of the mastoid process with retention of pus within the mastoid cells, when a permanent remission of the symptoms have not been brought about by Wilde's incision. The operation ought to be performed without waiting for symptoms of cerebral irritation or pyemia.

2. Recurrent swelling of the mastoid region, which has undergone temporary recession; or has led to abscess formation with or without fistulous openings in the integuments, even though no threatening symptoms exist at the time.

3. When after discharge of an abscess in the mastoid region, examination with the probe reveals a fistulous passage in the bone. Besides these generally recognized indications, the author considers the operation called for—

4. If with inflammatory processes in the ear, severe pains which resist all other treatment be present in the corresponding side of the head, even though no inflammatory appearance can be detected over the mastoid region.

In certain cases of tedious otorrhea the obstinacy of which is not sufficiently accounted for by the condition of the Eustachian tube and tympanum, and which resist long-continued and approved treatment on the ordinary lines, the discharge being offensive and mixed with cholesteatomatous masses or bony particles, even where no conspicuous changes can be discovered in the mastoid region, the author has recourse to operation; experience having taught him

that after removal of the cholesteatomatous masses or granulations which are frequently present in the antrum or mastoid cells, the otorrhea ceases and recovery takes place.

Sometimes, moreover, small circumscribed areas of inflammation exist in the mastoid process, which maintain the otorrhea and are inaccessible to ordinary modes of treatment. These are exposed by the operation and recovery is thus brought about more readily.

In connection with the two last-named indications, the operation acquires an exploratory significance, and under the modern favorable auspices of antiseptic surgical treatment, it may the more readily be undertaken on account of the danger which is always associated with a continuance of the disease.

255 South Seventeenth Street.

DISCUSSION ON THE PAPERS OF DRS. BRYAN AND TURNBULL.

Dr. C. H. BURNETT—I would like to ask Dr. Bryan whether anything had been used beside poultices and the Politzer bag?

Dr. BRYAN—In the first case the man was in a very low condition and could not give much information, but I understood that there had been only poulticing up to the time I saw him. In the other case there had been instillations of peroxid of hydrogen.

Dr. BURNETT—In the histories of all the cases reported as acute otitis media followed by acute mastoiditis I can read between the lines that the mastoiditis is a secondary infection, and in some cases I can see that the ear was over treated and secondary infection followed. I believe that in most instances the secondary inflammation was caused by the use of peroxid of hydrogen. Acute mastoiditis following otitis media has become much more frequent since the introduction of peroxid. You can imagine that erroneous ideas of treatment some people have, by one instance. I once found that a patient of mine, a physician, from whom I had removed the ossicles, had been for a year in the habit of cleansing his ears with his own saliva. I am sorry to say that nearly all the articles on this subject state nothing as to the treatment before the patient was seen by the aurist. I believe that cases of acute mastoiditis, complicating acute otitis media, are artificial results of improper irritative treatment and not the necessary result of the primary disease. They are instances of secondary infection due to the introduction and retention of morbid germs, by the irritative treatment of the primary inflammation and I know of no agent so efficient in forcing pyogenic germs into the inflamed ear as the expansive, energetic hydrogen binoxid.

Dr. J. A. STRUCKY—I have seen many cases of acute mastoiditis caused by the use of peroxid of hydrogen in middle ear troubles, especially in acute otitis media. I consider it a dangerous remedy, and it is not right to use it in these chronic cases, unless there is a large opening.

Dr. MYLES—A coagulum of the mucoid substance and the peroxid is formed and is left in the recesses, from which it can not be washed out.

Dr. A. B. RANDALL—My experience has been in absolute conflict with much that has been stated. I must speak a word in defence of the Politzer bag, the syringe and peroxid of hydrogen. They are in constant use in my practice. While I have been reproached with the fact that I have a considerable group of mastoid cases to operate on, I will ask anyone to point out a case of mastoiditis as a primary cause. These cases are almost all taken from the practice of other men. I have never seen any evil results from my vicious habits. The proper employment of the Politzer inflation in the early stages of otitis media is of great value; its abuse has no place whatever. The use of peroxid of hydrogen is limited ordinarily to the acute cases. The perforation is commonly small, especially in children. When the hot douche has not given good results I have taken care that my peroxid should go into the very places where it is said to do so much harm. We have bad results when the peroxid does not penetrate. With the use of the intra-tympanic syringe, carrying the peroxid into the cavity so that it bubbles out at the nose, I have seen these cases go on to rapid recovery. While I do not advocate this as a routine treatment, I have no fear as to the peroxid, and believe that it should be more widely used, especially in Europe where it is hardly known. Cases of the type mentioned by Dr. Bryan sometimes occur with peculiar frequency in the experience of some men. They are by no

means as rare as is sometimes supposed. I have had perhaps twenty or twenty five of them, and my assistant, Dr. Hammond, has had eight or ten. The cases to which we have reference today are acute.

Dr. CLINE—I had a case in which I removed a large polyp from the external auditory canal. Later, when the patient was returning to a neighboring town, he had a chill on the road. He came under the care of a very good aurist, who for a week worked hard to save his life. There was inflammation of the mastoid cells. The doctor, I understood, had washed out the cavity with peroxid and had put something into the ear to stop the discharge suddenly. I believe that we should discriminate in our cases. If we have a large perforation we can use peroxid with more safety than with a small opening, but it must be used carefully.

THE CHAIRMAN—I would ask Dr. Burnett if he objects to the use of peroxid in chronic cases to the same degree.

Dr. BURNETT—I do not use peroxid at all, either in acute or chronic suppuration of the ear on account of its expansive force and the consequent risk of forcing pus into the middle ear cavities. It is perhaps less harmful in chronic than acute cases. We must regard the antrum as part of the middle ear, not the mastoid. Many acute cases will get well without mastoid disease. A natural siphonic action takes place between it and the antrum. When I was a medical student we never heard of mastoid disease occurring as a sequel of otitis media. Why should one man now see 100, 200 or 300 cases in a comparatively short time if it is a necessary result of ear disease? The so-called acute mastoid disease as a sequel is largely an artificial result.

H. D. HATCH, D.D.S.—I once had a lesson as to the explosive force of peroxid of hydrogen. In working on a tooth my instrument slipped up under the tissues, almost to the eye. The wound healed and was apparently all right, but later an abscess formed, well up toward the eye. There was no swelling around the eye, except this small point, and there was no wound in the mouth. I slipped a bistoury into the abscess and injected peroxid of hydrogen. Inside of twelve hours after my injection, which caused intense pain, the face was swollen and the eye black. I have ceased to inject peroxid into any cavity into which there is a small opening, except in some cases where I inject a little at a time and tease out the pus. I have had other cases where the mechanical force of the explosion gave great pain. Members of the dental profession use peroxid of hydrogen largely. I came to the conclusion last winter that it was unwise to inject it into a bone cavity.

Dr. BRYAN—I have seen serious results from the use of the Politzer bag and from the use of peroxid of hydrogen, but they were at the hands of operators who did not know how to use them. My object was not so much to advise the members of this Association against the use of these things as to urge their cautious use. I have thought it best to present these cases so that they might be an object lesson to those who are not so careful.

PHENOMENA OBSERVED IN TWELVE CASES AT VARIOUS STAGES OF THE OPERATION FOR SECTION OF THE INCUDO-STAPEDIAL ARTICULATION AND MOBILIZATION OF THE STAPES.

Read in the Section on Laryngology and Otology, at the Forty-eighth Annual Meeting of the American Medical Association held at Philadelphia, Pa., June 1-4, 1897.

BY E. B. GLEASON, M.D.

Clinical Professor of Otology in the Medico-Chirurgical College; Surgeon-in-Charge of the Nose, Throat and Ear Department of the Northern Dispensary, Philadelphia.
PHILADELPHIA, PA.

The ear in which the patient's hearing was the more defective was invariably selected for operation. The night before the operation the auditory canal was thoroughly cleansed, syringed gently with a solution of bichlorid, 1 to 1000, and occluded with a piece of iodoform gauze, which was allowed to remain in position over night. The drumhead was soaked for one hour before the operation in a sterilized 4 per cent.

solution of cocain, by means of a pledget of sterilized absorbent cotton, which was saturated in the solution and inserted into the canal in contact with the drumhead. After the primary incision through the membrana, the edges of the wound and the intra-tympanic membrane was touched from time to time with a sterilized 10 per cent. solution of cocain. All maneuvers subsequent to the primary incision were thus rendered practically painless.

The steps of the operation performed for the relief of tinnitus and improvement of the hearing, in twelve cases of advanced sclerotic catarrh of the middle ear that had not improved as the result of non-operative measures, were as follows: An incision through the clear part of the membrana, as close to the periphery as possible, was made from a point below the level of the malleus tip to the short process, and the flap thus produced was turned forward over the malleus handle. An attempt was made to mobilize the chain of ossicles by traction in various directions upon the lower portion of the long process of the incus. In the last six of the twelve cases operated upon, the tendon of the stapedius muscle was then severed and the attempt renewed to mobilize the chain of ossicles by traction upon the long process of the incus. The incudo-stapedial articulation was next severed and the stapes mobilized if possible by lateral pressure and lever-like movements of a cotton-tipped probe in contact with the head of the stapes. In the last of the series of cases, sufficient force was exerted to fracture the crura of the stapes; but in this case not the slightest improvement of the acuteness of hearing followed the operation. There were however no disagreeable after-effects.

In all but one case the operation was comparatively bloodless. In this instance, however, such a persistent hemorrhage followed the primary incision through the drumhead that the operation was abandoned. Two weeks afterward an opening was made through the membrana over the incudo-stapedial articulation, by means of a cotton-tipped probe dipped in fuming sulphuric acid, the articulation severed, and the stapes mobilized. The slight improvement of the hearing that resulted from this procedure was lost during the course of an otorrhea that persisted for three or four weeks after the operation, but the patient was cured of an annoying tinnitus. Suppuration did not occur in any of the other cases.

Each of the twelve cases operated upon in the manner described above had their hearing carefully tested both with voice and watch at each step of the operation.

In no instance did the slightest improvement of the hearing follow the incision of the drumhead and the turning forward of the flap. Although the evidence of twelve cases is by no means conclusive, yet the writer can not help suspecting that the idea that improvement of hearing in catarrhal cases with patulous Eustachian tubes would follow the mere excision of a portion of the drumhead is a myth, and that the improvement of hearing that was reported to have followed this procedure was due in all probability to incidental mobilization of the chain of ossicles. This suspicion becomes more plausible when it is called to mind that Sir Astley Cooper did his operations with an ordinary trocar, and that up to the time of Wilde, the favorite instrument for performing the operation was that of Fubrizzi, consisting of a small trephine with a cork screw stilet, by means of which not only a section of the membrana, but also a portion of the

malleus handle was usually removed. So inadequate was this instrument for the safe perforation of the drumhead that two deaths following the operation were reported, in London, by Dr. Butcher in 1846, and in these two cases, at least, it is probable that something more was accomplished by the operation than the mere removal of a disc of the drumhead and a most thorough mobilization of the ossicular chain.

It also seems probable that in many instances the improvement of hearing and relief of tinnitus reported as following the modern operation for the removal of the drumhead, malleus and incus, were the result of the incidental mobilization of the stapes. The only advantage in catarrhal cases of such a procedure over the operation described above, consists in the accessibility of the stapes for purposes of mobilization, which is probably more than counterbalanced by the constant exposure of the intra-tympanic mucous membrane to the danger of infection by pyogenic bacteria.

It was found impossible to improve hearing in any of the twelve cases by manipulation of the long process of the incus in the hope of mobilizing the incus.

Section of the stapedius muscle was accomplished, in two instances, with an audible snap and an immediate improvement of the hearing. In both cases, however, further improvement followed the subsequent incision of the incudo-stapedial articulation and mobilization of the stapes.

The amount of force used where no improvement of hearing resulted from the operation, was in all instances sufficient to endanger fracturing the crura of the stapes, which actually occurred in the last case operated upon. In this and others where no improvement of the hearing followed manipulation of the stapes, it is probable that ankylosis of the foot plate of the stapes to the oval window existed to such a degree as to render it absolutely impossible to break up the adhesions without fracturing the crura in the attempt. Politzer has proven by his experiments upon the cadaver that when bony ankylosis exists between the foot plate of the stapes and the oval window the crura are invariably broken in an endeavor to remove the stapes by traction.

The duration of the vertigo which invariably ensues in the cases where improved hearing followed manipulation of the stapes, varied in duration from a few moments to three days. One case was obliged to lie down three times during the manipulation of the stapes because of dizziness and faintness, which, however, lasted only a few moments. In another instance the patient staggered almost like a drunken man as he was led away from my office at the conclusion of the operation. His dizziness lasted only twenty-four hours.

In no instance did any permanent injury to the auditory apparatus follow the operation. In all cases where tinnitus existed, it disappeared after the operation. There was, however, only in five a noticeable and practical improvement of the hearing. In one, improved hearing for the voice did not entirely disappear until three years after the operation. In all cases improved hearing for the watch invariably disappeared within a few months, probably as the result of the reformation of adhesions. In one or two hearing notably improved both for watch and spoken words for a few weeks subsequent to the operation. It seems more than possible that the hearing might have been again improved in some at least of the

cases by incising the drumhead and remobilizing the stapes.

41 South 19th St.

DISCUSSION.

Dr. BURNETT—I have seen several cases of perfectly mobile stapes with total deafness, and total ankylosis of the stapes with very good hearing. I think that so far the operation can claim to relieve chiefly in cases of aural vertigo. These cases can often be treated successfully by intra-tympanic operation, either by Dr. Gleason's method or, as I prefer, by the removal of the incus alone.

Dr. RANDALL—We may properly hope for this operation a place equal in importance to that held by the operation for cataract in the surgery of the eye. There, in a large number of cases, lies the impediment to the betterment of the organ of hearing. More attention should be paid to the proper testing of hearing in these cases. Disappointments will greet us for a long time, as they have done in the past, as in the case of the operation for the removal of the drumhead, which a few years ago was exploited as the new treatment for all ear diseases. Even with great care and proper selection of cases, results will often be very disappointing.

Dr. TURNBULL—I feel as if I had been an advocate of the removal of the malleus. One of my cases was operated on seven years ago and her hearing is still good. She was very deaf indeed. The benefit may have come from the mobilization which attended this operation. In another case I operated on a lady who had suffered greatly with vertigo. The vertigo was entirely relieved and she has fairly good hearing.

Dr. BERNSTEIN—I have removed the incus in three cases, but I shall never do the operation again. In one case, for about three weeks after operation the patient's hearing was decidedly improved, but after that she had to use a trumpet. This has been my experience in the other cases also.

Dr. MYLES—I have rather opposed the removal of the ossicles. When cures from this operation are reported, it is not always stated how long the hearing remains improved. I know one man whom a distinguished aurist persuaded to have his ossicles removed, and for awhile his hearing was improved; but now he can hear nothing. Two young men came to me two years ago, whose hearing had been much impaired for about two months. I found large exostoses and complete nasal stenosis, and one of them had considerable adenoid tissue and subacute otitis media. I advised rest. One of the young men told me that he had come from the office of a distinguished aurist who had been almost violent in his efforts to induce him to have the ossicles removed. I advised them both to wait and try the rest treatment first, which they did. They both hear well today. If the ossicles had been removed, they would have heard better for a time, and would probably have been reported as remarkable cures.

Dr. GLEASON—Until a couple of weeks ago, I supposed the result I obtained in a case operated on two years ago was permanent, but the patient told me that all the improvement had disappeared. I would advocate this operation only after everything else has been tried.

OBSERVATIONS ON SOME PATHOLOGIC CONDITIONS OF THE NASO-PHARYNX.

Presented to the Section on Laryngology and Otology at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY EMMA E. MUSSON, M.D.

PHILADELPHIA, PA.

Believing that the presentation of cases having either special pathologic features or dependent on unusual causes, or amenable only to special lines of treatment, would be of interest. I have selected from my case book several groups of cases which have come under my observation during the past two years.

The first group comprises a number of cases of hypertrophied lymphoid tissue in the vault of the pharynx, all of which required for their relief operative interference. The points of interest in these cases, relate to the age and the character of the symptoms. Out of the last 230 patients in my case book, 34 had hypertrophy of the third or Luschka's tonsil.

Of this number eleven were from 15 to 20 years of age; eleven from 20 to 25; eleven from 25 to 35, and one 40 years of age. The age of the majority of these patients attracted my attention on account of the prevalent belief that these lymphoid vegetations are peculiar to children and disappear at the period of puberty.

Of these thirty-four cases, nine were complicated with profuse post-nasal discharges. In five instances the growth interfered with singing upper notes; in one, with elocutionary work and in one with ordinary school teaching.

Two cases were complicated with hay fever; two with mouth breathing; two were subjects to attacks of acute pharyngitis and tonsillitis, and two were subject to frequent colds.

Twelve cases were complicated with disturbance of the ear. Of these, three had marked deafness; three were moderately deaf; one had purulent otitis media; two acute Eustachian catarrh and three tinnitus and fulness.

The majority of these cases had post-nasal catarrh. The hypertrophied lymphoid tissue in at least 95 per cent. of the cases was entirely confined to the vault of the naso-pharynx. The growth varied in appearance and extent, from apparently smooth masses, one quarter of an inch in thickness to vegetations as large as those found in well marked cases in children. A number of these vegetations were connected with the Eustachian tube by synechiæ. Moreover in those cases complicated by diseases of the middle ear, the vegetations were fibrous in character while in those complicated by a profuse muco-purulent secretion, they were soft and friable.

Surgical procedures for complete removal of the growths, were followed by relief if not complete disappearance of all the symptoms except the deafness. There was a disappearance of the post-nasal discharges and of the seeming purulent rhinitis, and the patient was no longer subject to repeated colds and sore throat. The voice became more resonant in speaking and two or three notes were added to the upper register of the voice in singing.

Surgical interference which gives such brilliant results in early childhood, for the relief and cure of deafness, was in my cases followed only by slight if any benefit; not until after a long course of patient treatment of the middle ear disease was any improvement noticed. In those cases however in which the middle ear was but slightly involved and the symptoms present only at intervals a prompt cure was effected upon removal of the growths. Of the cases complicated with naso-pharyngeal secretions, four were of exceeding interest. In two of them the discharge from the nose and naso-pharynx was purulent, profuse and constant. In the two other cases the secretion was excessively profuse, but entirely mucoid in character. Three had a family history of gout and rheumatism, and had not yielded to prolonged treatment for nasal catarrh. In two the amount of lymphoid tissue was so small that I hesitated long before removing it; there was an entire absence of the gross appearance of adenoid growths, the vault of the pharynx showing only a thin sheet of lymphoid tissue. After the lapse of a year, during which there was no recurrence of the discharges, I felt that I had been justified in my operative procedures.

The methods resorted to for the removal of these growths were the forceps followed by curetting in the

larger number of the cases. In two only I employed the galvano-cautery.

In reviewing the literature on this subject I found an article by Dr. Farlow, in which attention is called to the mistake frequently made, that adenoid growths in the post-nasal space are peculiar to childhood and that they disappear at the time of puberty. He also emphasizes the fact that the deafness occurring in adults as a result of adenoid vegetations is but slightly benefited by their removal. Bryson Delavan is quoted in the *Annales des Maladies de l'Oreille* as saying that adenoid growths persist after puberty. Moure makes a similar statement. Chiari, in the *Annales* for 1894, states that out of 233 private cases and 152 clinical, 16 cases between ages of 20 and 30 had lymphoid hypertrophy of the third tonsil.

W. H. Bates of New York, published a history of five cases of deafness in adults due to adenoid vegetations of which the youngest was 24 and the eldest 55 years of age.

This group of cases suggests several queries, to which I have been unable to furnish any definite answers: 1, as to the causes of absorption or non-absorption of adenoid vegetations; 2, what factors determine a variable group of symptoms in cases apparently similar: *e.g.*, why should the middle ear be involved in only a certain percentage of cases?

The second group comprises a number of cases of chronic naso-pharyngitis associated with, if not dependent on, the uric acid diathesis, employing this term in its broadest sense as a disturbance in the equilibrium which should exist between the production and elimination of uric acid.

The feature of this group, to which I ask attention, is a probability of the uric acid diathesis being the underlying and causative agent. It was pointed out by Beverly Robinson, in 1888, that there was apparently a correlation between post-nasal catarrh, gastro-intestinal disorders and lithemia and somewhat later Harrison Allen described the gouty sore throat. At the present time most authorities are united in the opinion that the majority of cases of chronic naso-pharyngitis are either due to some disturbance of the digestive tract or are local manifestations of some constitutional diathesis as lithemia, gout and so forth.

While the obverse of this was demonstrated by Turck of Chicago, who found in the stomach bacteria of the same variety as those in the mucus of the naso-pharynx, these bacteria can set up acid fermentation in the stomach. Believing that many cases of naso-pharyngitis are but local expressions of the uric acid dyscrasia, it has long been my practice, to look beyond the local nasal condition and so treat the patients constitutionally with anti-lithemic remedies. With a view of determining whether there was a defective elimination of uric acid, I had the urine of seventeen patients suffering from nasal and post-nasal disease carefully analyzed, using Haycraft's method for the uric acid test and the hypobromid process with Marshall's apparatus for that of the urea.

The majority showed a marked change in the normal ratio between the uric acid and urea excreted; the disproportion ranging from one of uric acid to seventy-four of urea, to one uric acid to eight of urea. Five cases had two or three analyses made, always showing a disproportion between the amount of uric acid the urea excreted: in Luff's table of fifty daily eliminations of uric acid and urea of a healthy adult man on a mixed diet, the highest percentage of elim-

nation of uric acid was one to twenty-eight, the lowest one to fifty-five.

It was only in exceptional cases that I found any marked gastric disturbances. These analyses seemed to establish the fact that the presence of uric acid salts was the exciting cause of the naso-pharyngeal symptoms.

Most authorities, however much they may differ as to the formation or elimination of uric acid or the proportion which it should bear to the urea, admit that under certain conditions an undue amount is found in the blood; according to Levison and Luff in the form of a quadriurate, and in consequence is apt to be deposited at the point of least resistance. Luff in his *Gulstonian Lectures* states that uric acid deposits have been found in the mucous follicles of the pharynx. In the words of W. F. Dudley, the uric acid dyscrasia, like other dyscrasias, has localized areas of special selection for its clinical manifestations.

One such area appears to be the vault of the naso-pharynx. This region is rich in lymphoid and glandular tissue and susceptible to uric acid deposition and consequent irritation, with a change in the character of the secretion. This latter change may be the possible cause of the subsequent congestion and hypertrophy of the mucous membrane which, at first, is attended with a profuse secretion of mucous, and later by a blocking up of the gland ducts and an atrophy of the glandular tissue, to be followed by a diminution of water in the secretion, the formation of clots of mucus and adherent crusts.

It is at this stage also that the marked symptoms in cases of chronic middle ear catarrh begin to appear; previous to this time there has been but slight buzzing in the ears with a sensation of fulness lasting a short period of time. These attacks, however, become more frequent until the patient is conscious that hearing is gradually being lost.

The line of treatment was toward the correction of gastro-intestinal irritation or constitutional diathesis, in connection with that of the local condition of the naso-pharynx. It was only in the milder cases or those in the earlier stage of the affection that relief followed non-surgical methods of treatment. In all other cases the hypertrophied and granular mucous membrane of the vault and post-pharyngeal walls was curetted, with excellent results. In those cases where the disease had localized areas, probably due to the blocking up of the gland ducts, the galvano-cautery was used, followed by improvement only. Stazza argues that surgical measures only are applicable.

The third group comprises a number of cases in which acute follicular naso-pharyngitis was a concomitant of acute lacunar tonsillitis. The association of these two states attracted my attention several years ago. Since then it has been my rule to examine the naso-pharynx in all cases of acute tonsillitis, to determine the frequency and extent of the follicular inflammation.

In 50 per cent. there was a congestion and swelling of Luschka's tonsil with distinct points of follicular exudate. In about 40 per cent. of the remaining cases there was a congestion but no exudate.

Bosworth, in his book, refers to this possibility of an acute follicular inflammation of the third tonsil. This involvement of the naso-pharynx in acute follicular tonsillitis affords a ready explanation for the number of cases of acute inflammation of the middle ear which complicate these attacks.

The general practitioner would seldom err if he included the treatment of the naso-pharynx in all cases of acute infectious diseases of the pharynx and tonsils. A further argument in favor of the theory of the participation of the naso-pharynx in acute pharyngeal infections is that frequent cases of chronic post-nasal catarrh follow in the track of these attacks.

Moure, in the *Twentieth Century*, gives a detailed description of acute inflammation of Luschka's tonsil under the name of acute adenoiditis and, judging from the symptoms detailed, probably many so-called "colds in the head" would prove, on post-rhinoscopic examination, to be attacks of acute naso-pharyngitis or adenoiditis. And here I digress for a moment to call attention to two different phases a so-called cold in the head may assume, as the result of a constitutional dyscrasia; in one we have the preliminary stage of dryness and irritation followed by a profuse watery secretion, later becoming muco-purulent; but if the patient be a lithemic subject the stage of serous effusion is followed by a profuse mucoid secretion, tenacious in character, blocking up nose and naso-pharynx but never becoming purulent; resolution is prolonged beyond that of the ordinary cold.

Two cases of this description occurred in children of 14 and 16 years of age; one with marked family history of uric acid on both sides, on whom ordinary treatment for "cold in the head" had no effect, was put on a strict dietary and given potassium bicarbonate; speedy relief followed this treatment, along with marked improvement in the general health and freedom from colds.

I will close this paper with a description of three cases of direct infection of the naso-pharynx. The first, a student in the bacteriologic laboratory, accidentally broke a test tube containing a culture of streptococci, and although strict antiseptic precautions were immediately taken, within twenty-four hours there was an active purulent inflammation of the tissues of the naso-pharynx, and in forty-eight hours, when I first saw her, the mucous membrane of the naso-pharynx was so swollen as to almost entirely cut off the view of that region. The discharge into the pharynx was profuse, purulent and foul, the temperature 102 F., though probably higher during the first twenty-four hours. Culture tube tests of the discharge showed a colony of diffused streptococci. A long time elapsed after the disappearance of the purulent secretion and high temperature before reduction of the swollen mucous membrane took place.

The second case was a patient who, just recovering from an attack of acute rhinitis, superintended the opening of numerous cases of ostrich feathers in the raw state, packed in camphor; she was suddenly seized with a sense of suffocation and fainted. Two hours afterward I found the throat intensely congested; in twelve hours an acute naso-pharyngitis developed, with profuse purulent discharge and a temperature of 100 degrees F.; two days later the temperature was normal and the throat almost well. The patient was sent to Atlantic City; twenty-four hours thereafter there was a sudden rise of temperature and involvement of both frontal sinuses and the left antrum in an acute purulent inflammation. No cultures were taken. Is it possible that these two cases were like Stazza's, that of acute inflammation of Luschka's tonsil during an epidemic of influenza, or were they due to bacterial infection?

The last case is that of a physician who has been

treated several times this winter for attacks of acute adenoiditis (Moure) which came on after exposure to cases of diphtheria or acute sore throat; the lymphoid tissue, between the attacks, now remains chronically hypertrophied. The patient is about 30 years of age and still retains in the vault of the naso-pharynx a small amount of hypertrophied lymphoid tissue that was not thoroughly removed in an operation performed six years ago.

258 South 16th Street.

DISCUSSION.

Dr. RICHARDSON—Acute inflammation of the naso-pharynx antedating and occurring with acute inflammation of the tonsils is, I think, a much more common occurrence than we are apt to believe. I have seen a number of such instances and a number of cases in which the inflammatory changes have been limited to the naso-pharynx and the acute inflammation of the tonsil has not appeared at all. I saw one case where the whole vault of the pharynx had almost the appearance of an acute diphtheritic change, and there was no inflammation of the tonsil. I think it would be wise in all cases to examine the naso-pharynx carefully. I have for a long time observed that the uric acid diathesis has much more influence on naso-pharyngitis.

Dr. D. BRADEN KYLE—Luschka's tonsil is really a normal physiologic condition. In many cases inflammation is secondary and not the cause of the enlarged gland structure.

Dr. G. V. WOOLEN—I am not a bacteriologist, but I know that bacteria must be a cause of many of the troubles that we see. A chief function of the nose is to purify the air, and the impurities of the air which are largely bacterial in origin must influence the nasal conditions. Most people escape these troubles, and why? The conditions must be favorable for their development. When these are present the fact is expressed in acute attacks. Such conditions may be brought about by indiscretions of diet, or by the thousand other things that interfere with health. The pendulum has swung to the operative extreme. We must go back to the cleansing processes. Patients, themselves, can do much in this way, by thorough cleansing before meals, especially where there is uric acid trouble. We can not give too much attention to cleanliness, which is very closely akin to antiseptics. With a simple alkaline wash I have done much to prevent trouble.

Dr. CURTIS—In my opinion the uric acid diathesis is far from being a complication of the disease. We should consider that it is due to the waste product of an overworked brain, very possibly due to an enfeebled condition of the body.

Dr. WILSON—Did I understand the last speaker to say that he considered these conditions due to an overworked brain?

Dr. CURTIS—I meant the uric acid diathesis not the adenoid growths.

Dr. WILSON—We see uric acid conditions in patients in whom the brain does very little work. I think it is reasonable to believe that there is something in the system which manifests itself in many ways, and which admits of bacteria taking effect on the membranes.

Dr. JACQUES—Physical resistance is the important point to be remembered in treating these cases. The uric acid diathesis may be the means of bringing down the general resistance. If so, it is one of the exciting causes. It takes a number of factors to produce these conditions. The mouth is a perfect breeding place for germs all the time, but only when the physical resistance is reduced do we have the proper conditions for disease. Bring up the vital resistance of your patients to the highest point, then treat the pathologic conditions.

The CHAIRMAN—A constitutional condition which disposes certain individuals to lymphoid enlargements, especially hypertrophy of the faucial and post nasal tonsils, has long been recognized. We are accustomed to call it lymphatism for want of a better term. That this is or may be synonymous with uric acid diathesis seems to me a new idea. I would ask whether the author found uric acid present in cases of chronic enlargement of the lymphoid tissues, or whether it was only in acute inflammation of those already hypertrophied. There is a constitutional tendency to recurrence of these growths after removal. Operators have endeavored to do thorough work; but even then several years after, in certain cases, there has been a recurrence of the hypertrophy. This is especially apt to take place, however, if a thorough operation is not done. Concerning the effect on the hearing, I have had cases of practical recovery from long continued deafness after operating for adenoids, but there are other instances in which but little improvement takes place. We are apt to look for improvement

too early. Cases which have disappointed me at the end of a week or a month, perhaps, show marked improvement at the end of three months.

Dr. Musson—I did not intend to convey the idea that in my first group of cases the trouble was due to uric acid. In the second group I spoke of the uric acid diathesis, sometimes with a certain amount of lymphoid tissue. Where uric acid was present I did not commence curetting at once but tried constitutional treatment first. I feel sure that some of my patients who had uric acid trouble did not overwork their brains. All antiseptic precautions were taken in these cases. In adults I believe that curettement could be carried out without injury to the Eustachian tube or the surrounding tissues.

QUESTIONS REGARDING THE ETIOLOGY OF ADENOID VEGETATIONS AS FOUND IN THE NASO-PHARYNGEAL CAVITIES.

Presented to the Section on Laryngology and Otology, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY M. C. O'TOOLE, M.D.

SAN FRANCISCO, CAL.

That we possess no positive knowledge regarding the etiology of adenoid vegetations, as found in the naso-pharynx, can be ascertained by a brief study of the opinions expressed by writers on this subject. Scrofula, heredity, the acute exanthems, cold and dampness of climate and whooping cough, have all been mentioned as etiologic factors, while Gruber asserts that neither climate nor occupation appear to influence their development.

In a paper, "Suggestions Regarding Treatment of Diseases of the Ears and Throat in Children," read before the Medical Society of the State of California, April 1894, the following statements appear: "For the past three years, I have lost no opportunity of investigating the etiology of adenoid vegetations, and the results have been in every way confirmatory of former experiences. Five years ago, I removed adenoid vegetations from the pharyngeal vaults of three children, all of the same family; two girls and a boy, aged at the time of operation 3, 5 and 6½ years respectively. The mother incidentally mentioned to me, when speaking of her trouble, that she had suffered considerably with leucorrhœal discharges at the time of their birth. She was then six months pregnant. A confrère remedied the abnormal uterine and vaginal secretions. The infant was borne in due time. It is now 3 years old, but has no abnormalities in the pharyngeal vault.

Since this experience, I have invariably questioned mothers, having children with these growths, and have in every instance found that they had been effected with abnormal uterine or vaginal secretions at the time of the birth of the child so affected. From these observations I have formed the opinion that acute suppurative inflammation of the middle ear in infants is, in most cases, the result of contact with gonococci bearing, maternal vaginal secretions during parturition and that catarrhal secretions under like conditions, are responsible for the existence of abnormal lymphatic follicles and adenoid vegetations as found in the pharyngeal vaults of older children.

The writer, being aware that his experience on this subject is as yet too limited to admit of positive conclusions, would nevertheless venture the opinion that obstruction of the nasal passages during infancy and early childhood by the causes and in the manner indicated is the chief etiologic factor in the development

of post-nasal growths whether as adenoid vegetations or hypertrophied lymphoid follicles, also that subsequent asymmetrical development of the nasal structures and of the nasal cavities are frequently traceable to the same cause.

6 Eddy Street.

A CASE OF MYXEDEMA WITH PROMINENT NASAL SYMPTOMS.

Presented in the Section on Laryngology and Otology, at the Forty-eighth Annual Meeting of the American Medical Association held at Philadelphia, June 1-4, 1897.

BY A. H. CLEVELAND, M.D.

CLINICAL PROFESSOR OF LARYNGOLOGY MEDICO-CHIRURGICAL COLLEGE; SURGEON TO EAR, NOSE AND THROAT DISPENSARY, PRESBYTERIAN HOSPITAL.

PHILADELPHIA, PA.

The fact that the nasal condition was the only reason why this patient sought relief and that this seems to be so entirely dependent upon the general disorder leads me to report the history, which is as follows:

Mrs. I., age 38, was first seen Sept. 9, 1896. She complained of nasal stoppage with attacks of sneezing and watery discharge following an attack of grippe in May and persisting since then. For the past three weeks it had been worse. Examination of the nostrils at this time showed large boggy turbinates on both sides, rather worse on right, with a waxy paleness of the entire mucous membrane of the nostrils. Several constitutional remedies, as well as local applications, were tried in succession without the slightest effect on the condition. Oct. 26, 1896, frost having eliminated a possible hay fever and the hoped-for improvement not having occurred, I examined the nostrils again very carefully and was impressed by the waxiness of the membranes as contrasted with the condition found in ordinary rhinorrhea. It suggested to my mind a general rather than a purely local disease, and close questioning elicited the following more or less confirmatory history.

Family history: On the mother's side two aunts had attacks of asthma. A cousin of the father also had such attacks. No history of tuberculosis or of nervous disease, except rather far back on the father's side there was some consumption. The patient has always enjoyed moderately good health. She is married, the mother of four girls and one boy all living. The oldest is 13 and the youngest 5; all the girls have been more or less troubled with eczema. Since the birth of the last child the patient has had "abdominal trouble," but of what nature I did not learn. She has always had a nervous temperament; quick in action and thought. The bodily functions have always been regular with the exception of occasional bilious attacks and constipation. Menstruation has been and is still entirely normal.

While the nasal stoppage and sneezing were the symptoms which first compelled her to seek relief, she recalls that two years ago her hair, which before had been black and glossy, began rather suddenly to turn gray and become brittle. It did not come out to any great extent however. It is at present iron-gray in shade, and dry, but not coarse. The nails are dry and brittle, the teeth in fair condition owing to close attention. Her dentist has told her however, that the teeth were soft and easily broken. There are no fatty tumors, no moles or warts, no swellings in the supra-clavicular region. She has noticed no patches on the skin other than a scaly eczema behind the ear on either side.

The skin seems however generally somewhat thickened. My attention was particularly attracted to the color of the skin of the face. It was markedly white with a bright spot over each cheek. This is not constant nor is the redness of the nose, which she tells me is sometimes present. The lips are full and high colored, the brows and lashes both of good thickness. Except when she has a nervous perspiration the skin is dry. There is frequently a puffiness under the lids although no other signs of edema. The features are neither coarse nor broad. She has never noticed any watery edema either general or local. The abdomen has felt swollen on a few occasions, but that she refers to the abdominal trouble. The thyroid gland is of small size but is distinctly apparent. I have been unable to learn of any nervous symptoms other than an irregular feeling of weakness with coldness of the hands and feet. There is no paralysis, tremor, or inco-ordination. Sight, except for some hypermetropia, is good. Hearing is normal. Smell and taste are both considerably affected by the nasal stoppage. The voice is nasal in quality. Speech is not delayed nor does there seem to be any mental heaviness or slowness.

Examination of the blood showed: red blood corpuscles 5,800,000, leucocytes 4,625, ratio 1 to 1254, hemoglobin 65 per cent.

There have been no hemorrhages from the gums or nose. The urine showed no abnormalities. The temperature is 98.6 degrees. Appetite and digestion are fairly good. Feeling convinced from this history, that there was more than a local condition to contend with and as some of the symptoms of myxedema were present, viz.: dry thickened skin, capillary injection over the cheeks, dryness and brittleness of the nails and hair and possibly the appearance of the mucous membranes, I ordered dessicated thyroids gram 0.32. t.i.d. She was not seen again until Dec. 4, 1896, when she reported that the powders had relieved her very much. I had ordered only enough to last ten days, but she had had no return of the symptoms until two weeks previously. The prescription was renewed. When next seen, Jan. 18, 1897, she reported having taken thirty-two powders between December 4 and January 8. While taking them the nasal symptoms were almost entirely relieved. Examination of the nostrils shows lessening of the puffiness and waxiness. Since this date she has taken powders more or less regularly with considerable relief.

It will be seen that while the general symptoms were not absolutely confirmatory of myxedema they were marked sufficiently to induce me to try the therapeutic test and in view of the happy results attending this trial I think we can safely make the diagnosis,

1423 Walnut Street.

GENERAL AND LOCAL ANESTHESIA IN LARYNGOLOGY AND RHINOLOGY.

Presented to the Section on Laryngology and Otology at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY JOSEPH S. GIBB, M.D.

Professor of Diseases of the Throat and Nose, Philadelphia Polyclinic;
Surgeon-in-charge of the Throat, Nose and Ear
Department, Episcopal Hospital.
PHILADELPHIA, PA.

In March, 1889¹ a very interesting discussion on the proper form of anesthesia to employ in nose and throat operations, took place in London. The discussion developed the widest differences of opinion

among the eminent gentlemen participating in the debate.

It seems odd that notwithstanding our experience in these operations has so markedly increased since this memorable debate, there should still exist great differences of opinion.

This is to be deplored. While it is of very little moment as to the particular form of anesthesia an individual specialist uses in his practice, it is of vital importance as to the teaching of the great mass of our profession by whom these operations are being performed in increasing numbers year by year. If some order could be brought out of this chaos of opinion; a few plain and safe lines to guide the busy practitioner a good work would be performed.

For convenience of study the subject will be divided into four headings, namely:

1, Intra-nasal operations; 2, naso-pharyngeal operations; 3, pharyngeal operations; 4, laryngeal operations.

Intra-nasal operations.—Intra-nasal surgery has made prodigious strides since the advent of local anesthesia. Nor is this due alone to the fact that the comfort of the patient is less disturbed. By this method, we are enabled to follow each step of an operation deliberately and intelligently, and hence to do better work.

Under general anesthesia the patient is in the worst possible condition to make a satisfactory examination. The recumbent position (the only one tenable in chloroform and ether narcosis) is one unfavorable to proper illumination, an objection which has scarcely been overcome by modern electrical refinements.

The position and the anesthetic, both favor hemorrhage, which covers the field of operation and adds to the difficulties.

General anesthesia, therefore, is indicated in intra-nasal operations; 1, major operations, those in which large growths are to be removed, necessitating a considerable amount of dissection, and possibly involving the external tissues; 2, in large bony deflections of the septum, where it is necessary to break up the septum at its base; 3, in large bony spurs in which the relative position of the outgrowth to the surrounding tissues have been accurately determined; 4, congenital or acquired stenoses; 5, plastic operations.

The number of cases which come under the second and third groups, namely, deflections and spurs, are small, and one finds them growing less year by year as his experience in this work grows. It is seldom we know precisely the operative procedure we will follow in an individual case prior to the operation. For instance, in pronounced cartilaginous deflections, how frequently we find after the cartilage is freed a corresponding bony deflection, with perhaps exostoses and spurs.

We are not all favored with small fingers to enable us to determine by digital examination the extent and nature of deformities, nor are all nares of sufficient dimensions to permit such examinations to those so favored.

While breaking up a deflected bony septum or the removal of bony outgrowths are undoubtedly painful procedures, which pain no amount of local anesthesia can entirely annul, this discomfort is transient, and

¹ Discussion upon the paper of George Stoker on anesthetics in operations on the nose and throat, British Laryngologic Association, Wednesday, March 27, 1889.

the benefits accruing from a method which will enable us to have the field of operation under our view at all times greatly outweigh the haphazard methods we are obliged to pursue in general anesthesia.

There are, however, a number of conditions in which general anesthesia is necessary—which anesthetic shall we employ? In the discussion in London it was developed that chloroform had long been, and was still, in use in work of this nature. Dr. Silk believes that the routine use of chloroform is founded on the assumption that it is safest in children, and from which its use has extended to adults. Lennox Browne prefers the local anesthetic effects of cocain in intra-nasal operations, but gives a general anesthetic if it is indicated or desired.

He with Stoker, Silk, Dundas, Grant, and a number of prominent English laryngologists prefer the use of nitrous oxid in operations requiring but a few seconds. In those requiring a longer time nitrous oxid is given to produce insensibility and to avoid the discomfort of inhaling ether—the latter is then continued as the anesthetic.

In hospital work the plan of the London surgeons is ideal, but in private practice there are many difficulties in the use of nitrous oxid, and especially in operations at the bedside.

Chloroform can not be recommended for reasons which will be more fully discussed under naso-pharyngeal operations. Bromid of ethyl is too transient in its effect for these operations.

Ether then remains alone the safest and most reliable anesthetic.

The obstacles to the management of the patient which general anesthesia presents are in a measure met by care in position. The half-reclining or sitting position is not to be recommended. The one thing that would seem to justify such position in an intra-nasal operation would be that it is the most favorable in which to employ artificial light. Against this, however, is the utter uselessness of any light after the first incision, when the parts are covered with and obscured by blood. Indeed, in these operations one is guided almost entirely by the knowledge he has gained of the parts prior to the operation.

A very cogent argument against this position is its danger—one not to be lightly set aside, especially in the use of chloroform.

The Trendelenburg position, or one with similar objects in view, is without doubt the most satisfactory for the following reasons: 1, with proper electric appliances as good illumination may be obtained in this as in any other position. At our clinic at the Episcopal Hospital an ordinary incandescent light with a reflecting surface back of the globe is placed in the hands of an assistant and the light is thrown upon the field of operation at any desired angle. The various forms of electric head-lights may be employed with equal, perhaps, greater advantage; 2, this position causes the blood to gravitate to the post-nasal and pharyngeal spaces, whence it may be repeatedly removed by a sponge in the hands of an assistant, or, if at any time the blood flows too freely the head may be turned to one side and the blood allowed to escape from the opposite nostril or the angle of the mouth. This gravitation of the blood posteriorly not only lessens the danger of aspiration but it in a large measure frees the anterior portion of the nares, thus enabling the operator to have a clearer view of the field of operation.

General anesthesia in intra-nasal operations is but a sorry substitute for local anesthesia, and should be employed only when the necessities of the case urgently demand it.

We are obliged, at times, to meet the wishes and desires of our patients; some of whom prefer general anesthesia because the operation can be done without their consciousness. At the same time it seems to me a folly to undertake such operations merely to please the patient unless we are reasonably sure we understand beforehand every necessity of the case.

The larger number of intra-nasal operations being best undertaken under local anesthesia, we must now decide which of the few local anesthetics will serve our purposes best, and the manner of its use.

Cocain has held undisputed sway as a local anesthetic for about fifteen years and, in the main, leaves little to be desired. Those who have used it freely, however, have now and then observed effects which have given rise to anxiety, and a few fatal cases have been reported from its use.

It has always been a matter of doubt to me in these cases of cocain poisoning as to the part played by the shock of the operation. A nervous woman cuts her finger and faints at the sight of blood; this same woman should certainly be expected to faint during an operation on her septum. I believe that some of the cases which have been regarded as cocain poisoning are of this nature.

A very few can not be explained in this manner and we are forced to admit that in some subjects an idiosyncrasy exists to the drug.

More recently, eucain has been extolled as the equal of cocain in anesthetic power and, it is asserted, possesses no such tendency as the latter drug to produce intoxication.

Our experience with this new anesthetic is necessarily too limited to assert positively as to the latter claim. There is no doubt in the writer's mind as to the validity of the former.

In an article published in the *Philadelphia Polyclinic*, Jan. 23, 1897, the author gave an experience of six months use of this drug in the clinics of the Episcopal and Polyclinic Hospitals. It was found to have equal anesthetic power with cocain, both as to intensity and duration of anesthesia in the larger number of cases.

Its power to reduce engorged turbinates was also equal to that of cocain. In the pharynx, while it possesses equal anesthetic power to cocain, it lacks those unpleasant suffocative, choking sensations which the latter drug at times induces. It is, therefore, much pleasanter in its effects in this locality. In no case were any symptoms approaching intoxication induced.

These results have been confirmed by a riper experience. Eucain is now used at my clinics in all operations in the nares, naso-pharynx and pharynx, except in those few instances in which cocain seems to have a better effect.

Its use in the larynx has been abandoned because cocain has equal anesthetic power and is slightly less irritating and hence less apt to produce annoying and troublesome spasms.

The pleasantest manner of obtaining anesthesia in the nasal chambers is as follows: First spray both chambers with a 2 per cent. solution of whichever anesthetic we elect, to obtain tolerance for the harsher

methods to follow. After waiting for one minute saturate a small pledget of cotton with a 4 to 10 per cent. solution of the drug and allow it to lie at the site of operation for from five to eight minutes.

Antipyrin in 5 per cent. solution has been found to intensify and prolong the anesthetic effect of cocaine or eucaïn; therefore, if the projected operation promises to be a tedious one after the removal of the tampon of cotton, a spray of antipyrin (5 per cent.) may be passed through the nasal chambers.

Antipyrin also has a decided hemostatic effect and in operations upon the septum or the posterior turbinates, parts that are quite vascular, this drug will prove to be an agent of decided advantage. It is, however, much too irritating for use in the nasal chamber, unless preceded by the free use of eucaïn or cocaine.

With these two reliable local anesthetics the rhinologist is well provided, and intra-nasal surgery is robbed of much of its terrors.

Naso-pharynx.—The most frequent operative procedure the surgeon is called upon to undertake in the naso-pharynx is that for the removal of adenoid vegetations from the vault.

There is great difference of opinion existing among surgeons regarding anesthesia in these cases.

Some viewing the operation as trivial, eschew the use of anesthesia in any form; others advise a local, and still others always employ a general anesthetic.

Probably much of this confusion and difference of opinion arises from an improper selection or arrangement of the class of cases.

In deciding upon the use of an anesthetic we should be influenced by the particular form of operation we are to employ and also by the age of the patient.

In adults and children of riper years who may be properly controlled these growths are best removed by means of the postnasal forceps.

These instruments should never be employed under general anesthesia, save by those thoroughly familiar with work of this nature and then guided by a finger insinuated back of the soft palate; this latter precaution is only possible to those having small digits, and hence the application of this method is limited.

The use of the forceps without the aid of the mirror in a space hidden from view has always seemed an unsurgical proceeding and especially since we have the means at our command to bring the parts thoroughly under the eye and to follow every step of the operation.

In those cases, therefore, of hypertrophy of the pharyngeal tonsil in adults or older children, in which it seems preferable to employ the postnasal forceps, the operation should be performed under the local anesthetic influence of eucaïn or cocaine and by the aid of the rhinoscopic mirror. There are many adults and older children either too nervous or with pharynges ill adapted for rhinoscopic work, these then will come under the same rules as those to be presently adverted to in the case of children.

By far the larger number of cases of adenoids occur in young children. The most popular methods employed for their removal are the curette, the fingernail or both combined.

In selecting an anesthetic, or in determining whether or not to use one, the surgeon is influenced by the estimate he attaches to the operation. In the hurry of life and in oft-repeated successes he is apt to regard this as a trivial operation and one unworthy of much

time consumed in the performance. Considering the proximity of important structures and the possibility of injury to the same, does this seem good judgment?

A general surgeon would deem it the height of imprudence to operate on a case and, especially if an anesthetic were considered necessary, dismiss it with little or no directions. He would rather have the patient remain in bed at least for a day to avoid any possible complication by means of chilling the surface, a contingency very possible to a child going into the open air a short time after an operation.

Adenoid operations are of daily occurrence in our clinics with and without the use of anesthesia and patients are dismissed with little instructions. It may be said that few accidents happen as a result of such methods. It is true we see few complications, but can we be certain they do not occur among a class of patients notoriously difficult to keep in view? Have we not seen acute inflammatory troubles of the middle ear follow this operation? Is it not possible that the apparent return of the trouble within a short period of time may be due to inflammatory conditions induced by exposure after the operation?

It has always seemed that the best interests of our little patients would be served were we to regard these operations of sufficient importance to demand at least one day's stay in bed.

These views have been borne out by my experience. At the Episcopal Hospital those cases treated in this manner have been free from complications of any sort and the results have been most satisfactory.

The operation of curettement of the pharyngeal vault is a painful one; slightly less so by the use of eucaïn or cocaine. It is therefore scarcely a humane procedure without an anesthetic in young children. To forcibly hold a nervous, irritable child and subject it even for a few seconds to severe suffering is a great tax to the nervous energies of that child and might lead to serious consequences.

The pain together with the gagging produces such contraction of the pharyngeal muscles as to place the parts in the most unfavorable position for good and thorough work.

General anesthesia should be employed in the removal of adenoids for the following reasons: 1. The operation can be performed in a more efficient and satisfactory manner. 2. It is attended with less danger of depressing effects to the nervous system of the child. 3. It serves as an extra inducement to treat these as surgical cases requiring care in the after-treatment and enables the surgeon to keep the patient in bed at least one day and thereby conduces to a successful result.

The operation can be done so quickly that the anesthetic which seems eminently suitable for these cases is nitrous oxid gas, the effects of which are transient.

In the London Throat and other hospitals in Great Britain this is the anesthetic employed, and in the discussion in London, already adverted to, the consensus of opinion was in favor of the use of this gas.

Dr. Silk² prefers it because it is pleasant, safe and can be administered in every position of the patient. No previous preparation is necessary and the recovery from it is rapid and perfect and the after-effects nil.

Lennox Browne³ uses no uncertain language in his advocacy of nitrous oxid gas in these operations. He

² Silk: *Journal of Laryngology*, London, 1889, lxi, p. 177-181: 238-242.

³ Browne: *Med. Press and Circular*, London, 1893, n. s., lvi, p. 136.

says: "The rapidity with which the patient can be anesthetized by gas, the almost constant absence of any unpleasant after-effects, the exceedingly short interval required for complete recovery of consciousness in addition to the incalculably greater safety on general grounds of its administration over any other agents, not only constitute strong arguments for its employment where the time required for the completion of the operation does not exceed from forty-five to fifty seconds, but actually renders the use of other agents culpably unjustifiable."

Nitrous oxid has had more or less extensive trial in this country and is well thought of by those familiar with its use. In hospital practice, and especially if care in the after-treatment follows its use, nitrous oxid leaves little to be desired as an efficient and safe anesthetic in the removal of adenoid growth in young children. In private practice, however, the cumbersome nature of the apparatus necessary for the production of this gas renders its use awkward, save in office work and here its use can not be recommended for reasons already stated.

Impressed as the writer is with the advantages of treating these as any other surgical cases, where it is possible to do so, we must needs search for an anesthetic safe and reliable which may be employed at the bedside.

Chloroform has long been used and especially by the English surgeons.

The chief reasons for its use have been that it is pleasant in its effects, was supposed to be harmless in children, quick in its action and free from unpleasant after-effects. Bosworth in the recent edition of his work favors this anesthetic.

When it is considered that no less than nine deaths occurred in England in one year from the use of chloroform, it should cause the surgeon to hesitate before employing it.

Dr. Silk, the anesthetist for the Great Northern Central Hospital clearly and forcibly states the advantages and disadvantages of chloroform in these operations. I quote from his paper: "I believe that the routine use of chloroform is founded upon the assumption that it is safest for children, a general proposition with which I in no way agree, and from which I fancy its use has extended to adults. Other advantages claimed for it are:

1. That it is simple to administer, and the resulting narcosis is easily maintained. It does not come within the scope of this communication to point out that these advantages are much exaggerated, but even if this were not the case I hardly think that the convenience of the operator should be placed above the safety of the patient.

2. That the bleeding and turgescence of the mucous membrane is less than when ether is used; but even if this were true the difference, as I have already pointed out is so slight that this advantage almost sinks into insignificance.

3. That the primary narcosis is more profound. This should I think be classed rather as a disadvantage, inasmuch as the zone maniable, to which I have already referred, is in respect to chloroform very narrow, and therefore even if no respiratory embarrassment prevailed, its use is always attended with a certain amount of risk; much more is this the case when the comparatively pure vapor which accumulates at the back of the throat may be inhaled at any time and is quite beyond our control.

The objections if not numerous are weighty:

1. I can fully endorse the view that chloroform administrations are always a source of anxiety to the anesthetist and in some instances of narrow escapes to the patients, and this is much more the case in naso-pharyngeal operations. On account of the accumulation of the blood at the back of the throat, and consequent interference with the respiratory functions, the heavy chloroform vapor speedily collects above the larynx, in a nearly pure or highly concentrated state. Hence the attacks of syncope and apnea which so commonly occur without the slightest warning, when chloroform is being administered. Its slight diffusibility, too, tends to permit of its accumulation in the lungs, and is accentuated by the respiratory failure. Hence the attacks of syncope and apnea occurring as they frequently do, some time after the administration has been withdrawn.

2. The after-effects of chloroform are often very prolonged. Such immediate effects as nausea, the loss of blood swallowed, are probably no better and no worse than those attendant upon the administration of ether, but profound prostration and digestive disturbance are said to continue for days.

3. Its administration in any but the absolutely recumbent position is quite inadmissible.

Bromid of ethyl is highly thought of both by the German surgeons and a few in this country. So far as the quick action and pleasant effects are concerned, this drug seems peculiarly fitted for these operations.

Morgenthau¹ of Chicago reports the results in 100 cases of adenoids in which bromid of ethyl was the anesthetic employed, and refers to Moritz Schmidt of Frankfurt-on-the-Main as having used it in 200 cases.

Morgenthau thinks that bromid of ethyl should not be used in chronic heart disease, 1.85 c.c. for children and 2.9 to 3.7 c.c. for adults is sufficient. In from forty to sixty seconds breathing becomes stertorous and for two minutes the patient does not feel pain. He operates in the upright position with the head inclined slightly forward so that the blood may flow out of the mouth.

He finds that the anesthesia, operation and recovery takes from five to seven minutes.

In the 100 cases of Morgenthau and 200 of Moritz Schmidt no deaths and but few unpleasant symptoms occurred.

Bromid of ethyl has as advantages, quickness of action, pleasantness both in the administration and the after-effects. The unfortunate result of the first introduction of this drug in Philadelphia by the late Dr. Levis, in which two patients succumbed, has deterred the profession there from its use. It is claimed, however, by those familiar with its use that the drug is nearly as safe as ether and that the early deaths were due to imperfections in the manufacture or in the substitution of bromid of ethylene a much more dangerous product.

The testimony of so many worthy and careful observers would seem to warrant that this drug which has so many advantages, should have a more extended trial.

Ether is the safest and perhaps the most widely useful anesthetic.

It is often unpleasant both in administration and after-effects but these are of slight importance in the security one feels in its use and in hospital work; fol-

¹ Morgenthau: Ethyl Bromid, JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 1895, XXIV.

lowing along the practice of the London surgeons its use may be preceded by the more pleasant nitrous oxid gas.

In the use of ether in removing adenoid growth from the vault of the pharynx, the anesthetic should be used to complete relaxation.

The writer is not in sympathy with those who use it short of this stage and has many times witnessed operations which have been delayed and complicated by the struggles and cries of the patient.

Once complete relaxation and insensibility have been obtained the anesthetic may be permanently withdrawn and the operation proceeded with, uninterrupted by any movement on the part of the patient. Given in this manner it is quickly recovered from and is much less liable to produce vomiting and other unpleasant effects.

The same method of procedure is applicable in those cases in which it is found necessary to remove both the faucial and pharyngeal tonsils. Here, however, it is best to push the ether a little more thoroughly than is the case where the simple adenoid operation is done, for the reason that after excision of the tonsils some little time is consumed in allowing blood to escape from the mouth before curetting the vault.

Incidentally the position of the patient during these operations is of importance. The most satisfactory results are obtained in operations in the naso-pharynx in that position which places the posterior wall of the pharynx and naso-pharynx in the most dependent position. This is accomplished by the Trendelenburg position or a modification of the same. By this method we are not delayed by gurgling of blood in the pharynx and symptoms of asphyxia and the danger to respiration is at a minimum.

At the house of our patient the true Trendelenburg position is not always feasible. In this case all that is necessary to obtain the same result is to allow the head to hang over the edge of table or bed. The blood is sponged from the pharynx by an assistant, the patient is turned on the side and the blood permitted to escape from the nose or the angle of the mouth.

Pharyngeal operations.—Nearly all the operative measures the laryngologist is called upon to perform in the pharynx can be accomplished under local anesthesia.

Eucaïn is to be recommended in this locality. It causes less discomfort to the patient and it is also probably less likely to give rise to unpleasant general symptoms.

Hypertrophied tonsils, the most frequent condition calling for surgical interference in the pharynx, when uncomplicated by anenoids at the vault, may readily be excised without the use of a general anesthetic.

This operation is accomplished so quickly, with so little pain (which latter may be annulled by local anesthesia) and the work can be done so effectively that it seems an unnecessary complication to induce general anesthesia.

In nervous, irritable children in whom the shock of operation and the necessary restraint might prove serious to the nervous system of the child, transient anesthesia is to be recommended. Nitrous oxid is eminently useful in cases of this nature.

Hypertrophied tonsils, associated with adenoid vegetations at the vault should be treated in a similar manner to that spoken of in the discussion on the removal of hypertrophied pharyngeal tonsils.

Laryngeal operations.—All intra-laryngeal operations are performed under local anesthesia.

Cocain is preferable in the larynx, because its anesthetic properties are equal to eucaïn and it is distinctly less irritating and consequently less liable to produce unpleasant spasms. By local anesthesia the modern laryngologist is enabled to remove growths formerly deemed inoperable or only removed by splitting the thyroid cartilage, thus causing subsequent impairment of the voice.

The various major operations, such as laryngectomy, thyrotomy and tracheotomy, are accomplished under general anesthesia. Recently, however, a number of tracheotomies have been done with cocain injected along the line of operation as the only anesthetic employed.

This method may occasionally be possible in adults or in children already narcotized by prolonged dyspnea, but it would be exceedingly unwise to advocate it as of general utility in children, upon whom we are most frequently called upon to do this operation.

1804 Chestnut Street.

TONSIL AND ADENOID OPERATIONS UNDER ANESTHESIA BY NITROUS OXID, AND NITROUS OXID AND OXYGEN: A PRELIMINARY REPORT.

Presented to the Section on Laryngology and Otology, at the Forty-eighth
Annual Meeting of the American Medical Association,
held at Philadelphia, Pa., June 1-4, 1897.

BY W. E. CASSELBERRY, M.D., AND F. MENGE, M.D.
CHICAGO, ILL.

The desirability of an anesthetic that would obviate the general objections pertaining to chloroform and ether in operation on tonsils and adenoids has been the source of much research. The chief objection to chloroform lies in its danger; bromid of ethyl has scarcely attained any greater confidence; ether, while reasonably safe, is so prolonged in its effects as to be inconvenient for this purpose. Nitrous oxid alone has been employed by a few operators, notably at the Central London Throat Hospital, but the available operating period from a single administration is almost too brief for the satisfactory removal of both the tonsils and adenoids. Experience has proven this anesthetic, however, to be safer than any other and to possess the advantage of a rapid revival of the patient; therefore following Gardner, Hunt and Hewitt of England, and Van Arsdale of New York, we have sought to modify the action of nitrous oxid by the addition of oxygen in order to render it more available and less objectionable for this operation.

As regards the safety of nitrous oxid, it is estimated by H. C. Wood that it is given in 750,000 cases annually and we have been able to learn of but thirteen deaths fairly attributable to it.

The anesthetic effects of nitrous oxid gas were first noted by Sir Humphrey Davy, about the end of the last century, and it has since, from year to year, come into more general use.

Under nitrous oxid the respiration becomes slower and if the gas be pushed, a complete cessation of respiratory movements eventually takes place. The heart beats quietly, fully and regularly under this gas. The pulsations are somewhat slow in profound narcosis. There is, however, but slight danger from heart failure resulting from the inhalation.

In animals killed by nitrous oxid gas the heart goes on beating even after the respirations have quite stopped. It is therefore less important to watch the pulse than the respiration.

So it will be seen that in the administration of nitrous oxid, the respiratory tract is most involved, the respiration usually rapid from the excited condition of the patient, after a short though variable period of inhalation of from one to two minutes, becomes deep and even snoring, and a complete anesthesia with unconsciousness is produced, lasting from thirty seconds to one and one-half minutes. But accompanying this and keeping pace with it, we have all the phenomena of asphyxia, due to a deficiency of oxygen in the air passages and tissues of the body.

One of the most evident means of avoiding this formidable objection with its cyanosis, stertor and general asphyxiation, was the addition of pure oxygen gas to the nitrous oxid, but, however, in such proportion that its value as an anesthetic should not be impaired.

The question as to whether nitrous oxid is an anesthetic *per se* or depends upon the accompanying asphyxia for its anesthetic effect, has never been definitely determined. From the fact that anesthesia can be produced by the gas with from 5 to 12 per cent. of oxygen it would seem that nitrous oxid is, in itself, an anesthetizing agent, although even then the slight asphyxia usually induced doubtless serves to augment the anesthetic effect.

A number of combinations have been used by different authors with varying success. The late Prof. Paul Bert, by administering under increased atmospheric pressure a mixture of oxygen and nitrous oxid, succeeded in producing a prolonged and profound anesthesia, at the same time maintaining normal oxygenation of the blood. He used 20 per cent. of oxygen, for the reason that the same percentage exists in atmospheric air. He obtained the necessary atmospheric pressure by having built, a large glass operating chamber, in which he together with his assistants and the patient were hermetically sealed, the desired density then being regulated through the medium of an air pump.

Van Arsdale sought to dispense with this chamber by substituting a tight fitting mask, giving the gas with 10 per cent. of oxygen, under pressure, with good results.

Hewitt of London, after experimenting upon a number of cases, found a 12 per cent. oxygen mixture produced anesthesia after an average inhalation of 126 seconds, of 44 seconds duration, while the average quantity of gas used was $8\frac{3}{4}$ gallons.

Having seen a number of anesthetics for dental purposes, we used at first the pure nitrous oxid on several cases and found that the gas, when pushed to its physiologic effects, afforded an anesthesia sufficient for operating purposes of about forty-five seconds duration, so we at first abscised the tonsils, then re-applied the gas and finished the adenoids, practically, with a second anesthesia.

Then we tried a 25 per cent. oxygen mixture but after twelve minutes and no anesthetic effect, we substituted the pure nitrous oxid, the patient being fully under the influence, to loss of eye reflexes, in less than a minute.

After this, some six cases were operated on with an approximate 10 per cent. mixture and with two applications of the gas, the average time of the first admin-

istration being about four minutes, while that of the second was about two.

Then we still further reduced the amount of oxygen and anesthetized completely with an approximate 5 per cent. mixture without much cyanosis or asphyxia in an average of two minutes. We also found that this mixture so lengthened the available anesthetic operating time, that we could remove both tonsils and the adenoids with one application of the gas, this complete operation occupying about one minute.

This is essentially a time-saving operation, and to do it every detail must be arranged beforehand; every instrument that could possibly be of use must be within easy reach of the operator. We inserted the mouth gag, using an O'Dwyer gag, before beginning the anesthetic. The patient was then placed in our usual operating position on the lap of an assistant, the head being on the assistant's left shoulder. The operator then turned on the gas from both cylinders, filling the intermediate rubber reservoir, whence the mixture was conveyed to the patient through a rubber tube to a snug-fitting mask, allowing absolutely no air to enter, this mask being held tightly over the nose and wide open mouth of the patient by the operator until the full effect of the anesthetic had been reached, recognized as with other anesthetics, by unconsciousness, loss of eye reflexes, etc.

The mask being removed, the patient is ready for operation. Both tonsils were at first abscised, in half the cases by a Mathieu and the other half with a Casselberry tonsillotome, and the adenoids were then immediately removed by a Gottstein curette. This operation can be performed without undue haste in one minute in the average uncomplicated case, but we do not wish to be understood as advocating such a quick method in every case, for when the tonsils are bound down by adhesions or other complications exist which require time and deliberation during the operating, then nitrous oxid is not a suitable anesthetic.

We have operated on fifteen cases in this manner; all were children, the youngest being $2\frac{1}{2}$, the eldest 11 years of age, five were boys and ten were girls, and all but one case were afflicted with both enlarged tonsils and adenoids. The patients were in all degrees of excitement, but immediately after the first two or three spasmodic inhalations they became calm and the respirations were full and regular.

The appended schedule gives the time of the first inhalation, time of operation on tonsils, the second anesthesia, the "adenoids" and age.

	Anes- thetic.		2d anes- thetic.		"Adenoids."		Age.	Gas mixture.
	1	2	1	2	1	2		
I	2 min.	1 min.	1½ min.	1 min.	4 yrs.	N ₂ O

XIV	3 "	1½ "	1½ "	3 "	4 "	N ₂ O 95 O 5		
XV	1 "	1½ "	1½ "	3 "	3 "	N ₂ O 95 O 5		

The apparatus required is rather cumbersome and heavy and consists of the face piece or mask, the rubber reservoir and the cylinders of oxygen and nitrous oxid. The mask is made of a metal frame which is covered by rubber, which at its edge, at the point of contact with the face, is in two layers and may be inflated. It is fitted with an expiratory valve as well as one whereby the gas may be turned on or off.

The rubber bag or balloon has a capacity of five gallons and serves as an approximate measure of the amount of gas consumed as well as for the mixing of the gases and on it, also, we made the necessary pressure to force the gas to the patient. This apparatus we purpose modifying by the substitution of a cylindrical gasometer for the rubber bag.

Nitrous oxid gas is now put into the liquid from under high pressure and keeps in this condition indefinitely, being placed in steel bottles. Oxygen in copper cylinders is now well known, while rubber tubing, with a junction, forms the connection with the bag.

The advantages of this mixture of gases over chloroform and ether are: 1, the absence of danger; 2, no preparation whatever is necessary; 3, the upright position usually desired may be safely assumed; 4, hemorrhage seems in no way to be affected by it; 5, the time of the whole proceeding is greatly lessened, from an hour and a half to as many minutes; 6, the after-effects, the vomiting and retching, are entirely obviated, and the patients may be safely removed to their homes within fifteen minutes.

It would only be fair to state the disadvantages that have occurred to us: 1, somewhat cumbersome apparatus required; 2, greater number of assistants desirable; 3, haste with which it is necessary to operate.

In reference to the haste, after some experience with the method, the operator finds that he has more time at his disposal than he at first thought possible.

We would say in conclusion, that we have in nitrous oxid mixed with a small percentage of oxygen, an anesthetic that is relatively devoid of danger, taking only a few minutes to administer, and giving a sufficiently long narcosis for the ordinary tonsil and adenoid operation and which is particularly suitable for dispensary use.

DISCUSSION ON PAPERS OF DRs. GIBBS AND MENGE.

Dr. ROE—Some years ago, before cocaine was introduced, I used nitrous oxid gas for small operations and particularly cauterizing operations in the nose, but since cocaine was introduced I have abandoned its use altogether. Nitrous oxid gas and bromid of ethyl are serviceable only in operations requiring but a few moments for their performance; whereas in operations that are at all prolonged they are entirely insufficient, and cocaine, chloroform, ether or some other less evanescent anesthetic, either local or general, must be resorted to. In some cases the operation for the removal of adenoid growths and also enlarged tonsils can properly be performed in from forty-five to sixty seconds, but in many other instances the conditions are such that it is absolutely impossible to properly perform the operation thus quickly; therefore nitrous oxid gas or bromid of ethyl are adapted only to a limited class of cases. In adults and older children I have found cocaine anesthesia quite sufficient for these operations, but in young children I use chloroform only. For hospital and clinical work, nitrous oxid gas and bromid of ethyl simply have the advantage of expediting matters somewhat. I have not only had no trouble from the use of chloroform, but have had most excellent results and have not felt the necessity of using bromid of ethyl, which is sometimes troublesome to procure perfectly pure, or of bothering with the cumbersome apparatus which the use of nitrous oxid gas requires. In children the use of chloroform is very simple and perfectly safe. It affords ample time for the performance of the operation, and with the proper manipulation of the child there is no danger of the inspiration of blood into the trachea, nor are there any other conditions that contraindicate its use.

In adults, the chief danger in the use of chloroform lies in the concentration of the vapor or in the exclusion of sufficient oxygen, and it is to obviate this danger that oxygen gas mixed with chloroform vapor is employed. Three years ago, while in London, I procured a new apparatus for administering chloroform, devised by Krohne & Sesemann, and since that time a similar apparatus has been made by George Tiemann & Co. of New York. The mask in this apparatus is so arranged that there is free ingress through the center for atmospheric air, while the chloroform is propelled into it, in the form of vapor, by passing the air through the bottle containing the chloroform. When there is prospective danger from the use of chloroform, oxygen gas can be substituted for the ordinary atmospheric air forced through the chloroform liquid in the bottle. By the employment of this apparatus, the use of chloroform is not only rendered perfectly safe for children, but also for all adults in whom there is not some physical complication to contraindicate its use.

In Paris they use chloroform entirely as a general anesthetic and it is not considered dangerous. I have in a number of instances seen the Parisian surgeons push the chloroform far beyond the point that we would consider safe and the patients recover all right.

We may reasonably conclude that the use of nitrous oxid gas and bromid of ethyl as anesthetics is of special service in those adenoid, tonsillary and nasal operations in children and nervous and sensitive adults which can be quickly performed, and especially in clinical and hospital work, in which it is necessary or desirable to dispose of the cases quickly; but that in many of these same operations, which can not be so expedited and at the same time properly performed, other anesthetics, as ether or chloroform, must be resorted to.

Dr. MARTINDALE—My knowledge of the use of nitrous oxid has been limited to the observation of 100 cases in the Central Hospital of London. My personal use of nitrous oxid is limited to the external auditory canal and peritonsillar abscess. My adenoid operation requires more time. Dr. Mackenzie has published his impressions as to the use of cocaine in the nasal passages in connection with general narcosis. Since then it has been alluded to by Dr. Cohen and others. I have found it a valuable adjunct, and several of my colleagues in Minneapolis have found it useful. I would not undertake an extensive operation on the naso-pharynx without first spraying it with a solution of cocaine. The use of the general anesthetic is attended with less danger.

Dr. ROE—Cocain does not seem sufficient to take away the pain. Bromid of ethyl makes the patient half unconscious, so that he is conscious of the operation but feels no pain.

Dr. SCHEPPEGREGG—I would use bromid of ethyl where an operation can be done in a short time, as there is comparatively less danger in a shorter anesthesia. If I can not complete the operation with the short anesthetic, I give chloroform. Some nine months ago I substituted eucaim for cocaine. I have used bromid of ethyl for four or five years in all cases of short anesthesia, without bad effects. Everything should be ready beforehand in these operations. Where children are old enough to have the gag placed in the mouth without exciting them, it should be done beforehand. If this is not possible, give the anesthetic to a slight extent, then apply the gag and complete the operation. I oppose prolonging the anesthesia to operate on both tonsils and adenoids. I have operated in this way on a patient over 18 years old, and have seen severe hemorrhage. In case we have this complication we should limit ourselves to either the adenoids or the tonsils. In using bromid of ethyl it is important to get pure preparations. In one case a druggist sent me nitrite of amyl. I have nothing to say against nitrous oxid except that it requires such complicated apparatus. Unless some good reason can be found against bromid of ethyl, I prefer to use it if the pure article can be obtained. I know of no fatal results.

I think the difficulties of operating in the sitting position have been rather exaggerated. I always operate in that position, with an assistant holding the head of the patient well forward. The advantages over the Trendelenburg position are marked, because the patient sits in front of you, and the relation of the parts is better maintained.

It would be impossible for me to do adenoid operations in forty-five to sixty seconds. I think many of us would require a longer time than was mentioned in the paper.

Dr. BLISS—I say emphatically that adenoid operations on children ought to be done under general anesthesia. In Europe and in many parts of this country it is done without anesthesia, but I consider this almost cruelty. If you do not complete the removal at one operation, you will not induce the child to submit a second time. We may remove adenoid vegetations in a child under 1½ years old without anesthesia, because the

nervous system is not so highly developed, and the child will not remember so well. For general anesthesia in children I prefer chloroform. It is just as safe as ether and more agreeable. Since bromid of ethyl and nitrous oxid have been used, I have tried them in a number of cases. One objection is that we never know exactly when the right moment has come to operate. In some cases when the amni drops there is sufficient anesthesia, but in others there is not. Also you have to introduce the gag before operation. With a timid child the preparations beforehand will make him dread the operation. The reflexes are not abolished and the child may scream. An operation under general anesthesia should be done either in a hospital or at the house of the patient, and not in the office.

As to the nitrous oxid, I operated some years ago on a dental student who had hypertrophy of the turbinal. I did it in the anesthetizing room at the dental college. I was surprised to see how easily it could be done, and I was also alarmed at the almost carelessness with which the dental surgeons produced a case of cyanosis. In the fifteen or sixteen cases in which I have used nitrous oxid, it was given by a dentist. The patient has the disadvantage of seeing the preparations beforehand, and unless he has fortitude he gets frightened. General anesthesia should always be used in adenoid operations, and the method is largely a matter of choice. I think that chloroform with the addition of 5 per cent. of oxygen will be of value.

Dr. MYLES—The shock of giving a child ether I think is as great as that of doing an operation. In regard to the operation, we may make an actual diagram and topographical description of the disease, then line out as much as nature intended us to have of the tonsils. If you operate on children who have fairly good tonsils, you will have very little trouble. If you pass your finger up into the posterior nares and tonsils and the child has adenoid growths, you will also find large hypertrophy of the lingual tonsil and fauces. But to run a curette up there and remove all this tissue takes ten or fifteen minutes. One firm sweep upward and backward will remove a larger amount than you can get by any other process. The instrument must be suited to the case, and must be of proper size and properly sharpened, so that it will engage the tissue and not bounce over it. I do not think it right to subject the child to an anesthetic, especially to ether when the work can be done without it. We should use the simpler methods.

Dr. STUCKY—I am opposed to general anesthesia in operations for adenoids except in very rare cases. There is more shock in giving the child an anesthetic than there is in the operation. Make an application of cocain and then place a sheet around the child, fastening it behind and before, and slip in the mouth gag. After that there will be no more resistance or screaming and you can perform the operation thoroughly and with less shock. Keep the patient quiet for several hours after operation.

Dr. MERRICK—I think there is more danger of hemorrhage with general anesthesia. I operated on a child four years old, and curetted under cocain. There was bleeding from 12 that day until 12 at night. If I had used a general anesthetic I think the child would have died. I have operated in about 100 cases and have used nitrous oxid gas in two and chloroform in one. A very severe hemorrhage followed the use of the anesthetic. I investigated the proceedings of laryngologic bodies for one year. I found five cases of death from tonsillotomy. I did not find a single case where fatal hemorrhage occurred except where a general anesthetic was used. Meyer used no general anesthetic. In my clinic I never think of using one. I have a grooved table upon which the patient is held by an assistant and the operation is completed in one minute. The child may cry. Two minutes after the child is released it is all right. Only in very extensive cases is a general anesthetic justifiable. You can do these operations, certainly in 95 per cent. of cases, without any risk except that of hemorrhage.

Dr. BLISS—I have just left a little patient, five years old, whose throat I have curetted without any anesthetic whatever. He was just as fond of me as though I had not done it. A great deal that is said on this subject is overdrawn.

Much of this adenoid tissue is absolutely physiologic, and the line of demarcation must be drawn with great caution. In the younger cases we can hardly use the visual exploration with any satisfaction. Digital exploration is almost a necessity. In the matter of curettement, the finger is far better than any other instrument. We have the pulp of the finger as a protection and can squeeze out the adenoid tissue with a minimum of bleeding and danger. If a large mass is to be removed, we can do it in nine cases out of ten without an anesthetic. Where we have a large operation to do we must have a general anesthetic, and in Philadelphia this will usually be ether.

Dr. MACKENZIE—Unless indications are strongly to the con-

trary, and unless the child is rebellious, I prefer to operate on adenoid growths without an anesthetic. It takes longer, but I make a more complete operation. It is sometimes necessary to prevent recurrence, to employ vigorous curettement. If so I sometimes resort to an anesthetic, generally to bromid of ethyl. If a general anesthetic is to be administered to children, I prefer to give chloroform first until comparative quiet is secured, and then keep up the narcosis with ether. I have used bromid of ethyl in these cases for years, and have never had an accident. The drug must be pure, however. It can now be obtained in hermetically sealed tubes. Care must be taken also to exclude the air. If these precautions be taken I think it is perfectly safe. As to the removal of adenoid growths and both tonsils in forty-five to sixty seconds, in my hands the operation would not be complete. It seems to me absolutely impossible in a very short time to reach every nook and cranny of the naso-pharynx and to be sure that the extirpation is complete.

Dr. MARTINDALE—As to using ether in the upright position, I have seen one death from a dentist using ether in his dental chair, and that is enough to deter me from using it in that way. I have used nitrous oxid with very pleasant results. After one becomes accustomed to the alarming appearance of the patient I think there is no danger; and if Dr. Casselberry has added oxygen, which increases the narcosis and lessens the danger, this will be an ideal anesthetic. But the majority of cases which need an anesthetic should be placed under narcosis for a longer time than one minute.

Dr. COBB—I will say a word in the defense of ether in the upright position. In the Massachusetts General Hospital, ether has been used. In the last eight years we averaged over four adenoid operations a week, and there has not been one death. I think that is fairly good evidence of the safety of ether.

Dr. GIBBONS—I would call attention to the necessity for knowledge as to forced respiration, etc. A patient who does not recover from ether or chloroform does not die for some time. We should do something to restore animation, besides the ordinary traction of the tongue. A surgeon is criminally responsible if he has not a regular apparatus for this purpose, or at least a common pair of bellows. If he has a compressed air tank he can resort to that. He should certainly have oxygen. Forced respiration should be kept up for at least six hours. Life will sometimes come back after six hours when it will not after four or five. If you have nothing better, insert the compressed air tube and push it down into the trachea. You may find it convenient to do tracheotomy. At least 90 per cent. of adenoid growths can be removed without a general anesthetic. When a general anesthetic is needed I use chloroform and nitrous oxid.

Dr. GIBB—In Philadelphia we largely use ether. Our experience with bromid of ethyl has been such as to deter us from its use; but I think the bad results were largely due to the impurity of the drug. The same objection may be offered to nitrous oxid and bromid of ethyl, the short period of anesthesia. This is especially true if the combined operation for adenoids and hypertrophied tonsils is undertaken. There are many adenoids that it is not necessary to remove at all, and still others can be removed by so simple an operation that no anesthetic is needed. But in cases of large adenoid, I still believe that ether is the most desirable form of anesthetic. Nitrous oxid and bromid of ethyl give too short a time.

THE CHAIRMAN—The only way of harmonizing the diversity of views is the natural one of making a proper selection of cases. No fixed line of treatment could be laid down for all cases even to the anesthetic preferred. There are adenoids which can not be removed in one, two or three minutes, and there are those which can, or at least which can be sufficiently removed for practical purposes. There are some cases where it is desirable to make the operation on the faucial tonsils and adenoids at different times, but usually it is best to do a combined operation. Complications may arise, but you would find no general surgeon willing to make two bites of a cherry on so small a surgical measure, especially if the operation be done under a general anesthetic. You can treat hemorrhage just as well in the case of a child under anesthesia as without.

Dr. Menge has taken an extreme position in saying that nitrous oxid with oxygen is absolutely free from danger, for that is true of no anesthetic; it is relatively free from danger. There is also slight asphyxia, even with the oxygen. It is only intended for institution and office use, where the apparatus can be kept in readiness. As to operating without anesthesia, in some children it can be done very well and in others it can not. As to the citation relative to dangerous hemorrhage with an anesthetic, I have elsewhere reported a fatal case from the practice of a friend following tonsillotomy without an anes-

thetic. The child swallowed the blood and the hemorrhage was not observed until too late. If there is hemorrhage you can stop it better with an anesthetic than without. With nitrous oxid the anesthesia is so brief that the patient would have to be re-anesthetized by other means in the emergency of a dangerous hemorrhage.

SOCIETY PROCEEDINGS.

The Quarantine Convention of the South Atlantic and Gulf States.

(Concluded from page 490.)

FEBRUARY 11—MORNING SESSION.

The convention was called to order at 10 o'clock and the Chair announced that the order of business would be the discussion of the papers on "National Quarantine" and "A National Bureau of Health" (*vide JOURNAL*; February 26, p. 490).

It was ordered that the discussion of the report of the Committee on Resolutions, when made, be coupled with the discussion of the papers.

The report of the special committee on the resolution introduced by Dr. John B. Hamilton, relative to dangerous infected ports, to provide for the maintenance of a medical force at those ports and the calling of an international quarantine conference, was read. The report favored the adoption of the resolution and the drafting of a memorial to Congress to give it effect, and was unanimously adopted.

NATIONAL QUARANTINE.

The following is an abstract of the paper read on Thursday by Dr. H. B. HORLBECK, health officer of Charleston, S. C., and ex president of the American Public Health Association.

The subject of National quarantine is a function affecting the vital interests of the entire Nation, and it is a task which has its peculiar character, viz., the protection of the different States and municipalities, with the privilege of self government in those States and municipalities unimpaired.

It would appear that this condition is the pivotal point in the adjudication of National quarantine: To have furnished the fullest and amplest assistance and co-operation by the Nation and to permit intelligent and willing work by the State and municipality. The privilege of our self-control in these matters is the very foundation stone of our civilization, and the abrogation of the power of a municipality to be the final arbiter in her government of her health interest would be the destruction of a right which carries with it the most sacred duties pertaining to a congregation of human beings established under the constitution of the United States. *Salus populi suprema est lex*—The health of the people is supreme law, and should be the most absolute right of every municipality.

We therefore, in adding our modicum to "National quarantine," must above all interests have this sacred right and privilege carefully considered, and we say advisedly "considered." It is not our desire to have these privileges so absolute that an improper or inefficient fulfilment of such duties should not be a matter for adjudication. The rights and privileges of the municipalities being established, we are prepared for discussion of the relation of National influences in these matters.

The governing body who may have the control and guidance of National quarantine should ever be on the alert to have such general laws of quarantine as may be passed and of force carried into effect. We say general laws, and it is idle in addressing so intelligent and well informed a body to designate such laws which affect the general health of all collected bodies of human beings. Such laws should ever be of force, and as we understand the situation such federal laws are now and have been of force since the act of Feb. 15, 1893, and they are now dominant. All communities who are recreant to their sacred rights and privileges, should at once be brought to a realization of their shortcomings by the controllers of the National laws.

As I am a life-long resident in a sea-coast city, it is but natural that I should more particularly address you in reference to the requirements of the quarantine of such a city in its relation to National proceedings. As Charleston is affected by National quarantine, so are affected the cities of the South Atlantic and Gulf coasts of the United States. The diseases incident to one are incident to all, and the proceedings for the protection of health and for the non-injury to commerce are the same.

There is something new in the situation that is the threat-

ened additional powers that are embodied in Senator Caffery's bill, known as Senate Bill No. 2680, additional powers to be given to the Federal Government, practically under the control of the Marine-Hospital Service.

This concise and forcible bill of less than two hundred lines sweeps away all privilege of State or municipality of making any laws as to quarantine, and vests this duty in the nominal hands of the Secretary of the Treasury, as it is a matter of fact that this department of the treasury is under the Supervising Surgeon General of the Marine-Hospital Service. They are simple words, these commencing lines of Senate Bill 2680, but they are ruthless as to any further privilege of the governmental bodies thinking what may be best for the interests of a State containing a seaport city.

The act of Feb. 15, 1893, entitled, "An act granting additional quarantine powers and imposing additional duties upon the Marine-Hospital Service," is destroyed. In the very initial sentence this bill, No. 2680, condemns all privileges of cities judging for themselves or enacting laws for their procedure, and says of the act of Feb. 15, 1893, that it shall be amended by striking out the following words in Section 1: "And with such rules and regulations of State and municipal health authorities as may be made in pursuance of or consistent with this act."

The rules and regulations deemed wise and efficient, and made at the suggestion of State or municipal boards of health, are swept out of existence, and the Secretary of the Treasury "shall make such rules and regulations as are necessary to prevent the introduction into the United States of any infectious or contagious disease from any foreign port or place, or the spread of such diseases from one domestic port to another," etc., . . . "to be enforced by consular quarantine and customs offices of the United States, and the State and local quarantine officers of the United States" . . . "with the proviso that they shall not discriminate against any port or place." The laws are to be made by the Secretary of the Treasury and practically carried out under the power of the Supervising Surgeon-General of the National hospital service. Was there ever a law made that was not open to differences of opinion as to its meaning? The State Board of Health of Louisiana were for years trying to enforce their laws as to the collection of dues contracted for quarantine procedures. Is it to be the privilege of the Marine-Hospital Service to take the place of the supreme court of the United States? Who is to adjudicate the proper charges of quarantine procedure, are the same charges to be made in a port of a dozen entries in a year with ports having thousands of vessels entering their harbors, like New York, Boston, Philadelphia or New Orleans? All such matters should surely be in the hands of the ports interested.

On page 3 we find that when the Secretary of the Treasury shall deem it necessary, etc., incoming vessels shall be inspected by a National quarantine officer designated or appointed by the Secretary of the Treasury on recommendation of the Surgeon General of the Marine-Hospital Service, and such vessel can not be admitted to entry without the certificates of said officer that the United States quarantine regulations have been complied with.

The quarantine laws for the great cities of the United States are to be made (practically) by the Marine Hospital Service, and if not satisfactorily carried out in the opinion of that service, an officer is to be sent, recommended by them, to forbid entry as they see proper. Was ever such power granted? Is it the meaning of this bill that every port must yield to this overwhelming power, and pass over their cities to the Marine-Hospital Service for quarantine government?

On page 6, line 25 says whenever yellow fever, cholera, plague or typhus has passed the quarantines of the United States . . . the quarantine regulations of the United States, prepared under the direction of the Secretary of the Treasury, shall be supreme and have precedence of State or municipal laws, rules or regulations, and the President is authorized to enforce the same."

On page 6, lines 14 and 15, we find, "and to prevent unnecessary restrictions upon interstate commerce." Any person violating a prohibition or a permit from the Federal authorities shall be deemed guilty of misdemeanor and shall be subject to a fine of not more than \$1000 or imprisonment for not more than twelve months, or both, at the discretion of the court.

This is the *summum malum*. Therefore, any health officer who shall disregard a permit which he regards dangerous to his community, shall wear stripes in a common prison or penitentiary and pay a fine which may beggar him.

There are two quarantines, one in the interests of health and one in the interests of commerce. The quarantine interests of health and of commerce are ever at variance. It must be so.

The laws governing success in commerce are inexorable. To forbid entrance to or from a city for merchandise means a stagnation which carries with it while it lasts loss to commerce, and so we are able to have this bill to prevent unnecessary restrictions upon interstate commerce. To have the *ipse dixit* or advertisement from any person representing a National service that perfect disinfection has been carried out only should convey with it the fact that it is so stated. The privilege of recognizing whether such procedures are believed to be effective and of avail should belong to the community to whom it is desired to consign such shipment. Are the causes and methods of prevention of yellow fever so well known that we can definitely say this person is harmless, and that package will cause no peril? We believe we can say so with certain procedures thoroughly carried out, but are such procedures possible when the commerce of a great city becomes a factor? We believe not, and with every disposition and inclination to fulfil such requirements we believe the Federal Government has not yet reached a position to perfectly disinfect great train loads of men or merchandise.

We have tried to discuss the bill of Mr. Caffery with all fairness, as it affects National quarantine. We believe it to be a most pernicious bill, wrong in spirit and wrong in letter. The act of Feb. 15, 1893, is, in our opinion, wholly sufficient for our present requirements; it is full as to foreign requirements, and it says as to local procedures:

"Section 3. That the supervising Surgeon-General of the Marine-Hospital Service shall, immediately after this act takes effect, examine the quarantine regulations of all State and municipal boards of health, and shall, under the direction of the Secretary of the Treasury, co-operate with and aid State and municipal boards of health in the execution and enforcement of the rules and regulations made by the Secretary of the Treasury to prevent the introduction of contagious or infectious diseases into the United States from foreign countries, and into one State or Territory or the District of Columbia from another State or Territory or the District of Columbia; and all rules and regulations made by the Secretary of the Treasury shall operate uniformly and in no manner discriminate against any port or place; and at such ports and places within the United States as have no quarantine regulations under State or municipal authority, where such regulations are, in the opinion of the Secretary of the Treasury, necessary to prevent the introduction of contagious or infectious diseases into the United States from foreign countries, or into one State or Territory or the District of Columbia, and at such ports and places within the United States where quarantine regulations exist under the authority of the State or municipality which, in the opinion of the Secretary of the Treasury, are not sufficient to prevent the introduction of such diseases into the United States, or into one State or Territory or the District of Columbia, the Secretary of the Treasury shall, in his judgment it is necessary and proper, make such additional rules and regulations as are necessary to prevent the introduction of such diseases into the United States from foreign countries, or into one State or Territory or the District of Columbia, and when said rules and regulations have been made they shall be promulgated by the Secretary of the Treasury and enforced by the sanitary authorities of the States and municipalities, where the State or municipal health authorities will undertake to execute and enforce them; but if the State or municipal authorities shall fail or refuse to enforce said rules and regulations, the President shall execute and enforce the same and adopt such measures as, in his judgment, shall be necessary to prevent the introduction or spread of such disease, and may detail or appoint officers for that purpose."

We regard the protection of a city against the introduction of disease to be a privilege, a great right and a great duty, and we protest against the assumption of such rights, privileges and duties by any branch of National service. It is our conviction that the State and municipal authorities should be built up, not torn down and made subservient. These health authorities should be encouraged in every way to feel their responsibilities, and should be encouraged to take a quick and lively interest in all matters pertaining to the health of the Republic, and they should be encouraged to feel their responsibilities, and as long as they indicate by their labors that they are striving for the public good they should be given the fullest opportunity of carrying out the health laws as they are understood by competent sanitarians. The duties of the Marine-Hospital Service are now vast enough to satisfy the ambition and desires of any body of men. Under the laws they must co-operate with, not entirely supersede.

Such aid in all great epidemics and emergencies as they may give should be actively, generously and thoroughly bestowed. Such a field, although not limitless, is vast, and in it the

Marine-Hospital Service may find ample room for honorable service. We re-echo the sentiment that National quarantine should be co-operative, not autocratic.

The discussion on the papers above referred to was opened by Dr. John B. Hamilton of Chicago, who spoke on the subject of "A National Bureau of Health." He spoke of a bill drafted by the AMERICAN MEDICAL ASSOCIATION relative to the establishment of such a bureau and asked the endorsement of that bill by the convention. He said the bill had been drafted for the benefit of the whole country. He read extracts from the provisions of the proposed bill and explained those provisions. He said he would take naught from the powers of the Marine-Hospital Service, and in the bill providing for a commission of public health it was intended that the Marine-Hospital Service should be the executive arm of the proposed commission. This bill, while giving National authority, provided for full co-operation by State authorities.

Hon. JOHN E. GRADY of Appalachicola followed. He said that for a long time he had been of the opinion that all matters of quarantine should be under control of the federal government. He said that those States bordering on the Gulf or Atlantic are not the only ones interested in the matter of quarantine, and spoke of the difficulty of explaining to a Norwegian shipmaster the differences of the quarantine regulations of the various ports, and said that the correction for these differences lies in uniformity of quarantine laws. Such uniformity will put each port on an equal footing.

MAJORITY REPORT—COMMITTEE ON RESOLUTIONS.

Dr. HARALSON of Mississippi then read the following report: The Committee on Resolutions respectfully recommend the adoption of the following:

Resolved, That the Quarantine Convention of the South Atlantic and Gulf States invite the attention of the Congress of the United States to the Senate Bill No 2680, introduced by the Hon. Mr. Caffery, as not conducive of the sanitary interests of the country. The convention does not regard the bill as necessary or wise. The powers proposed to be conferred upon the Secretary of the Treasury are extreme and dangerous. We therefore respectfully urge that the said bill do not pass.

Resolved, That the Senate Bill No. 3433, a copy of which is transmitted herewith, introduced by the Hon. John C. Spooner, creating a commission of public health prepared by a committee of the AMERICAN MEDICAL ASSOCIATION, endorsed by the American Public Health Association, having the merit of covering the entire sanitary field and providing a uniform system of quarantine of the Federal Government with the co-operation and advice of every State board of health in the Union, would, in the opinion of this convention, be wise and satisfactory. We therefore respectfully urge its passage.

The bill providing for the raising of a commission to study and investigate the disease of yellow fever, and providing for an appropriation and emoluments and expenses of that commission was endorsed by the committee.

The resolution for a conference of the health authorities of the South Atlantic and Gulf States to formulate a code of quarantine rules and regulations and promulgate the same was endorsed by the majority and its adoption recommended.

[Signed]—H. B. Horlbeck, B. Smith, J. L. Ludlow, U. O. B. Wingate, J. L. Horsey, J. M. Holloway, S. A. Robinson, J. F. McShane, A. R. Reynolds, J. C. Egan, H. H. Haralson.

Col. W. E. KAY of Georgia then read a minority report signed by himself and Capt. J. M. Falkner, and moved its substitution for so much of the majority report as refers to the Caffery bill:

MINORITY REPORT OF THE COMMITTEE ON RESOLUTIONS.

Mr. President, we beg to report the following resolution, which we ask to be substituted for the majority report of the Committee on Resolutions:

Resolved, That it is the sense of this convention that the Congress of the United States should immediately enact such legislation as will result in the establishment of a National uniform system of quarantine, relating to the regulation of commerce with foreign nations between the several States, with due regard to the rights of the various States.

Resolved, further, That it is not the purpose of this convention to endorse any plan or criticize any legislation now proposed, but simply to place on record its belief in the necessity for uniformity of such enforcement as is only possible under National supervision, leaving the plan and details to our Representatives in Congress.

[Signed]—W. E. Kay, Georgia; J. M. Falkner, Oklahoma. Hon. R. H. CLARKE of Mobile then offered the following substitute for both reports:

CLARKE'S SUBSTITUTE.

Resolved, That it is the sense of this convention that Congress should enact laws to provide for an efficient maritime quarantine, to be uniform and impartial in its application to the different commercial ports of this country, so as to give no one or more of them undue commercial advantage over the others, leaving to the States to prescribe and enforce additional reasonable safeguards of the health of their communities, provided that such State action shall not unreasonably obstruct commerce.

2. That Congress should aid the several States in establishing and maintaining uniform reasonable and efficient quarantine laws for regulating interstate commerce, leaving to each State adequate power to protect, as it shall deem best, the lives and health of its people.

3. That Congress should leave exclusively to the States the regulation of their internal commerce, and the provision of such quarantine or sanitary laws and regulations as they may deem advisable to that end.

4. That, in the framing of quarantine laws and regulations, and their enforcement, Congress should avail itself of the learning, experience and ability of the medical profession in the fullest measure possible.

Hon. EDGAR H. FARRAR of New Orleans moved the reports be divided and that the last two resolutions as to the appointment of a commission to investigate yellow fever and as to the conference of the States be taken up first; adopted.

That portion of the report relative to a yellow fever commission was adopted without dissent.

That portion of the report relative to a conference between the South Atlantic and Gulf States, to formulate a code of quarantine regulations, was then placed before the convention.

Dr. M. CUNNINGHAM of Birmingham moved its adoption.

There was some discussion as to the limit to be placed on the debate on the reports of the Committee on Resolutions.

On motion of Mr. JOHN B. KNOX of Anniston, after accepting amendments by Colonel W. E. KAY of Georgia, the leaders of the minority and majority reports and substitute were allowed twenty minutes and all others ten minutes, the debate to close at 3 o'clock.

Asked about the provision for the conference of the States, the chairman declared that it had been adopted.

The question then came up on the substitute offered by Hon. R. H. Clarke. He said the question is whether the convention should condemn the Caffery bill and endorse the Spooner bill. He said he had received an official copy of the Caffery bill and the Senate Committee's report, only one member of whom dissents from the recommendation that the substitute for the Caffery bill pass, and condemning the Spooner bill. He said the convention knew the influence of a committee report and if the majority report is adopted it will virtually say to the Senate Committee "you must reverse your action." We are an advisory body and we should not be too dictatorial, and we ought to avoid putting ourselves in the attitude the adoption of that majority report will place us. The Senate Committee has given more careful attention to those two bills than the members of this convention. He continued his argument against the condemnation of the Caffery bill, and said that he supposed the majority report condemned the original Caffery bill, every word, line and punctuation mark of which after the enacting clause, had been stricken out. The original Caffery bill had been condemned by the Senate Committee.

Professor SHANDS of Oxford, Miss., objected to the reservation of time by the leader of the minority report.

The convention voted that the twenty minutes applied at the beginning of the debate.

Colonel KAY then took the floor in support of the minority report. He inveighed against the acceptance of the Spooner bill as a *sine qua non*, and said that its adoption would wipe out the rights of the States in the matters of local quarantine. He said the provisions for a conference with State boards of health by the commission would be impossible of fulfillment. The vote of the Health officer of Maine, where there was never a case of yellow fever, would have the same weight as the vote of the Health Officer of Louisiana, and the adoption of the Spooner bill would be a very unwise step.

Dr. H. B. HORLBECK of Charleston then took the floor in support of the majority report. He said the Caffery bill was condemned because it is autocratic. The Committee had two bills before it, and carefully considered both the original and the amended bill for three hours. He claimed that it sweeps out the rights of the States to manage their own quarantines. It sweeps out the last atom of power that any State may have, and gives the Federal Government absolute control and says the law shall be supreme, and those who do not obey its mandates shall be amenable to a fine. Can a gentleman sitting in

Washington manage our quarantines. If I thought the Spooner bill had any such conditions I would vote against it right here on this floor. I am a health officer and my duty is to protect life, and I have nothing to do with commerce. The lives of the people are paramount to business. He characterized the Caffery bill as iniquitous. He endorsed the Spooner bill as earnestly as he condemned the Caffery bill, and discussed the provisions of that bill at length.

Dr. SANDERS moved that Nos. 32 and 33 be the special order for the evening session; adopted. These numbers are: "Epidemics and Quarantine from a Religious Standpoint," by Rev. H. C. SEMPLE of New Orleans, and "Epidemics and Quarantine from the Ethical and Humane Points of View," by Rev. GEORGE B. EAGER, D.D., of Montgomery.

After a discussion, participated in by Dr. Waldauer of Mississippi, Dr. Kohnke of New Orleans, Edgar H. Farrar of New Orleans, John B. Knox of Alabama, the resolution was passed under a suspension of the rules.

The discussion on the report of the Resolutions Committee was resumed, and Hon. E. L. Russell took the floor in support of Mr. Clarke's substitute.

Hon. F. C. ZACHARIE of New Orleans offered an amendment to the first section of Mr. Clarke's substitute, for the purpose of making it clearer, the amendment not altering the sense of the section. He then advocated the adoption of the substitute of Mr. Clarke, and at the conclusion of his remarks the convention took a recess.

AFTERNOON SESSION.

Hon. R. H. CLARKE's amended substitute adopted.

Mr. NORMAN WALKER of New Orleans introduced a resolution providing for the holding of the proposed quarantine conference provided for by the convention at Atlanta, in the week beginning April 25. An amendment fixing the date the first Tuesday in April was accepted by the mover. The motion was then adopted.

Hon. R. H. CLARKE then asked leave to withdraw his substitute and to substitute therefor another substitute. This request was adopted by the convention.

Colonel KAY then withdrew the minority report.

Dr. HORLBECK withdrew the majority report and moved the substitute be adopted; carried amid applause.

The amended substitute is as follows:

Resolved, That it is the sense of this convention:

1. That Congress be requested to provide for a department of public health as soon as practicable.

2. That it is the sense of this convention that Congress should enact laws to provide for an efficient maritime quarantine, to be uniform and impartial in its application to the different commercial ports of this country, so as to give no one or more of them undue commercial advantage over the others, and to be enforced by the several State and municipal quarantine or health boards, if they will undertake so to do, leaving also to the States the power to prescribe and enforce additional reasonable safeguards of the health of their communities, provided that such State action shall not unreasonably obstruct commerce.

3. That Congress should aid the several States in establishing and maintaining uniform, reasonable and efficient quarantine laws for affecting, but not regulating interstate commerce, leaving to each State adequate power to protect as it shall deem best the lives and health of its people.

4. That Congress should leave exclusively to the States the regulation of their purely internal commerce and the provision of such quarantine and sanitary laws and regulations as they may deem advisable to that end.

5. That in the framing of quarantine laws and regulations and in their enforcement Congress should avail itself of the learning, experience and ability of the medical profession in the fullest measure possible, and especially by way of an advisory council.

Dr. KOHNKE of New Orleans offered a preamble and resolutions as to popular education in hygiene, endorsing the purposes of the Louisiana State Sanitary Association, and recommending the establishment of similar sanitary associations, was adopted by the convention.

Mr. R. J. LOWE objected to the resolution and made the point of order that the resolution should go to the committee, but was overruled.

Dr. S. R. OLIPHANT, ex-president of the State Board of Health of Louisiana, then read a paper on

SANITARY INSPECTORS OF FOREIGN PORTS: WHAT IS BEING DONE AND WHAT CAN BE DONE IN THIS DIRECTION.

The Doctor outlined the use of inspectors in fruit ports and in other foreign ports on the lookout for cholera, yellow fever and other infectious or contagious diseases. He outlined the

duties of the inspectors in his opinion and said they should deal in facts first and in opinions afterward. He said the quarantine officer should never pass through his lines a shipment he would not receive in his own city. He spoke of the great benefits that had already accrued by reason of a system of medical inspectors.

Mr. ZACHARIE moved that copies of the resolutions adopted by this convention be forwarded to Congress, which was adopted.

A collection was taken up to defray the incidental expenses of sending out circulars and the chair guaranteed to raise by subscription the amount necessary to print the proceedings of the convention, amounting to \$63.35.

Hon. D. M. TAYLOR of Mississippi offered a resolution that each of the Spanish-American countries be invited to send one delegate to Atlanta, with a view of having a co-operative international quarantine system; adopted.

Dr. H. H. HARALSON of Biloxi then read a paper on "Medical Inspectors of Coast Towns and Cities, How Best to Provide For."

The Chair appointed the following Committee of Arrangements for the Atlanta convention: Collier of Georgia, Moody of Alabama, Renshaw of Florida, Horlbeck of South Carolina, Ludlow of North Carolina, Smith of Texas, Formento of Louisiana, Griffin of Mississippi. On Publication: Dr. Moody, Hon. Leslie E. Brooks and Erwin Chaighead of Mobile.

Dr. P. E. ARCHINARD of New Orleans then read a paper on "Recent Discovery of a Method of Early Diagnosis of Yellow Fever."

Dr. QUITMAN KOHNKE of New Orleans then read a paper on "What Steps Should be Taken in Dealing with First Case or Cases of Infectious or Contagious Diseases that May Reach our Towns or Cities."

Dr. FELIX FORMENTO of New Orleans then read

THE POLICY OF DEPOPULATING CITIES INFECTED WITH YELLOW FEVER: IF UNDERTAKEN, HOW BEST TO ACCOMPLISH.

He said: *A priori* and on general principles, we would probably all be inclined to admit that the early depopulating of infected cities, if practicable, would be the best and most efficient means of stamping out an epidemic disease at its very birth, by removing the elements necessary to its development. A fire without fuel will soon die out, the disease would soon come to an end for want of subjects. But is such a policy possible? Can it be carried out? Even with the good will and active co-operation of all the citizens of a town or village, is such a general exodus practicable? How and where could we find the physical means, the financial resources necessary, indispensable for the carrying out of such a measure? Who would furnish both the means of escape and of subsistence to thousands of families, and for an indefinite period?

As to a compulsory depopulating, to a forced exodus, even in the smallest of our communities, such a course is not to be thought of, is absolutely impossible in a free country like ours. No authority on earth would have the power, still less the right, to enforce it. The population of the smallest and most insignificant hamlet has natural rights and privileges, which can not be interfered with. In this question, the presence of yellow fever is not the only factor to be considered. The innumerable and varied family, social and commercial interests of modern life can not be overlooked, sacrificed to fear, justifiable or not, of a disease, however dreadful it may be; their ruin would be more of a calamity than the disease itself. I can not here abstain from protesting in the strongest terms against the shameful and humiliating measures inspired by terror and panic which have been witnessed all around us during the last epidemic. These measures of self-protection were as worthless and unscientific as they were cruel and tyrannic. Remnants of the practices of the dark ages, they are unworthy of our age and civilization. I never could understand why our people, so brave, so reckless and indifferent to danger, ready to take all sorts of risks by land and water, should become so timid, so frightened, so demoralized in the presence of a few cases of yellow fever. That disease has the privilege of inspiring more terror than any other, many times more terrible and fatal. This sentiment of fear is degrading and a worse evil than the disease itself, as it tends to lower the moral sense of a whole people.

This terror is entirely unjustifiable. In fact, yellow fever has lost much of its violence since 1853. That year the death rate was enormous, 3 out of 4! In 1878, it was 1 in 5; in 1887 it was 1 in 20, and in 1897 it was about 1 in 200.

General depopulating of a city or town, however desirable from a theoretic point of view, is, I repeat, of impossible realization. It never could apply to a large city. Voluntary exodus, which implies the necessary means to accomplish it, of

individuals and families should greatly be encouraged, especially at the very breaking-out of the disease. This depopulating is generally done at once, spontaneously, without waiting for the direction or control of health authorities.

During the existence of an epidemic no persons should be allowed to leave the infected locality for a healthy one, without taking proper sanitary precautions. These consist principally in permitting no baggage, but only scant wearing apparel, and in the thorough washing and disinfecting of the person himself.

Refugees should be brought to a camp of observation established in a convenient and healthy locality on the railroad outside of all contamination; there they would remain during the period of incubation; then a train from the town willing to receive them, and carrying clean, disinfected clothing, etc., would come to convey them to their destination. We could cite several instances in which, under similar precautions, the transfer was effected without any bad results.

There is a method of depopulating which is, perhaps, more productive of good than that of towns and villages. We refer to the early depopulating of the houses in which occur the very first cases of fever. This method applies to all infectious diseases and is the one followed in Germany for the immediate stamping-out of scarlet fever, typhus fever and other infectious diseases. To carry out successfully this plan, all necessary precautions should be taken in advance and be always in readiness, especially in those cities most exposed to infection. Special hospitals for the treatment of yellow fever, established in the outskirts of the town, should at all times be ready for the reception of patients, and camps of observation and isolation, one of the best measures instituted during the recent visitation, should also be fully prepared in advance. On the occurrence of the very first cases the sick should be removed to the hospital, and the well, living in the infected house, at once removed to the camp, and the house thoroughly disinfected. This is particularly urgent in crowded tenement houses and densely populated quarters.

EVENING SESSION.

Rev. GEORGE B. EAGER, D.D., of Montgomery, read a paper on

EPIDEMICS AND QUARANTINE FROM THE ETHICAL AND HUMAN POINTS OF VIEW.

He said: This question of quarantine has its distinctly legal and commercial aspect, which none of us would minimize, and which business men are naturally inclined to think the all-important ones. It has also its international, National and State aspects, and then its sociologic, scientific and sanitary aspects.

Quarantine in our own country is conceded to be very complex, ineffectual and defective. We have had ample illustrations of this fact within late years. Under its operations and abuses we have been called to witness the most humiliating atavistic tendencies of human nature and society. Poor human nature has shown in many cases a most shocking reversion to type. In one way and another our people have been guilty of the most barbarous cruelties. These cruelties have been shown especially in the enforcement of defective, various and unscientific local systems of quarantine that exist in our Gulf States.

With human nature what it is, and society as it is, crude and undeveloped in many of its elements, with much of our civilization proving itself, under stress of fear and selfishness, but a veneering, certain excesses of tyrannies will crop out. There are evils that are incurable at the present stage of our development. "What can not be cured, of course must be endured." But are there not many of the inconsistencies and inhumanities of the existing quarantine system that might be remedied? If so, all principles of justice, right and humanity call on us to address ourselves to this problem with all earnestness and unselfishness.

Admitting all that can justly be said on municipal and State rights and on the legal aspects of quarantine, one fact stands out, the recent conduct of quarantine affairs by local authorities was a scandal and a disgrace to civilization! The dread name of the disease alone seemed sufficient to terrorize the majority of our people and lead to the most brutal encroachment on inherent human rights, to the violation of nearly every law of the decalogue and to unreasonable and inhuman interferences with travel, transportation and trade. As a result of this contagious demoralization, not only was business absolutely paralyzed, but the States of Alabama, Mississippi, Louisiana and Texas, as we all know were almost wholly given over to terror and anarchy, masquerading under the name of "local" quarantine.

Let it be granted that the function of quarantine has to do with health matters, that it is the protection of the public from

an invading disease, that this is primarily the duty of the State; my contention is that all considerations of humanity require that its enforcement should be as free from complications, delays and harsh exactions as is compatible with efficiency, and that the expense to commerce should be reduced to a minimum. That a pest-ship, for instance, should be obliged to go out of its course a hundred miles or more to be disinfected, is a sufficient evil in itself; but that the sick, often without medical care, and the well, in constant danger of infection, should be penned up in the same vessel, perhaps for several days, is barbarous.

A system of quarantine that is just and humane, at the same time that it is efficient, should not only remove the sick to a hospital, but should provide means for comfortably caring for the well who have been exposed to infection, and should possess the necessary authority, force and apparatus for the speedy disinfection of vessels, baggage, merchandise and clothing.

In conclusion, if the abuses and cruelties and excesses complained of and all ideas can be checked, or in any degree cured, by the establishment of an improved and well adjusted National quarantine system, or by an enlargement of the scope, force and equipment of the Marine Hospital Service, then all principles of justice and humanity require that we should subordinate our local preferences, our too narrow or sentimental ideas of State rights, and our personal ambitions for position or greed for revenue, to the greater interests of the greater number.

Dr. CHARLES A. MOHR of Mobile then read a paper on "Agents and Methods of Disinfecting Houses, Cars, Freights, Baggage, etc., and the Classification of Freights as to their Liability of Conveying Infection." Dr. James M. Holloway of Louisville, on "To What Places may Refugees from Localities Infected with Yellow Fever Go, and how Should they be Managed and Cared For." Dr. Warren E. Anderson of Pensacola, a paper on "Quarantinable Diseases—What they Are and How they should be Dealt With." Dr. George A. Ketchum of Mobile, on "What may be done to Check the Spread of and to Exterminate Yellow Fever after it has Become Prevalent in a City." Surgeon R. D. Murray submitted a paper without reading on "Camps of Refuge and Detention." Dr. Maxime Landry of New Orleans, read a paper on "The Experiences of a Quarantine Officer in the Recent Epidemic."

Dr. SANDERS rose to a question of personal privilege and took occasion to vehemently deny the charge of making an effort to pack this convention with men against National quarantine. He said he sent the paper that originated the charge a 200-word telegram and a letter, which if they had been published would have swept away the charge. Another was the intimation that he had selected a large number of lawyers all on the same side of the question, which he denied, saying that he was entirely ignorant of what side any lawyer would take until he heard them address the convention. He said he appreciated the resolution adopted thanking him for his efforts in getting up the convention, but he feels under no obligations to the presiding officer for courtesies extended during the convention, as he had dissociated him from any part in shaping the policy of the convention.

The convention then adjourned *sine die*.

New Jersey State Sanitary Association.

(Continued from page 493.)

On Saturday the chief paper was

PASSAIC VALLEY DRAINAGE,

by W. T. HUNT of Newark, a son of the late secretary of the State Board of Health. The Passaic Valley has long been a source of trouble owing to the great need of some means of drainage for the number of towns which occupy its fertile plains. Many of these are large and important. All have long been urging some relief for the great foulness of the river owing to the escape into it of the sewage of these places, not only destroying the value of the water for drinking, but in many instances causing disease by the foul odors given off in its course. Hence after many efforts the legislature, in 1896, appointed a commission to consider the subject of its pollution and of a general system of sewage-disposal for its relief. Ten thousand dollars were appropriated for the purpose. The report of the Commission is one of great value, well prepared with maps and charts to show the true condition and the plans proposed for its improvement. Mr. Hunt was one of the Commissioners. He said: Passaic Valley sewerage is distinctively a sanitary measure and commands the attention chiefly upon that basis. It is, however, complicated in its engineering, its financial and legal aspects, and it is embarrassed by the diversity of interests affected, the antagonisms all such general measures arouse, and the imperfect knowledge with which the

subject must be approached. But when it has been established that this is a sanitary necessity the greatest step has been taken. For through the association of men such as constitute this body, through the individual labors of physician and engineer, and through the wise acceptance of new truths by courts and legislators, it has come to be recognized that sanitation has rights which give it precedence, and that the power which restrains crime and prevents contagion may also be asserted for public works which are necessary to health. If we may isolate the smallpox patient, we may also demand that a source of disease shall be removed; and the time is not distant when the public right to compel the private party to connect his house with a sewer will be followed by measures to require that communities should protect themselves by adequate sewerage systems. The right of self-destruction is no longer respected. The status of the movements for the relief of the polluted Passaic may be briefly mentioned. The commission reported to the legislature in February last, the Governor recommended prompt consideration and a joint committee was appointed to report upon the advisability of legislation at the next session. This committee has begun holding sessions in the cities interested, beginning with Bayonne. Let us look at the problem. The Passaic River becomes the Lower Passaic by going over a precipice at Paterson into the thickly settled district of a city of 100,000 people; its rapid flow is checked after a couple of miles by a dam at the city of Passaic where the sewage of 18,000 people is received: thence it is a tidal river receiving the sewage of Newark with 230,000 inhabitants, besides contributions from partially sewered towns in the distance between. In this drainage district there was a population of 436,423 in 1895, and the growth has since been rapid and gives every indication of continuing at a high ratio, since the facilities of travel have been largely increased. The estimate of the engineers of the Commission was that the population would be 1,458,000 in 1930, and those who have seen the strides made in the last five years will not challenge the figures. Now the Passaic has heretofore taken care of the sewage of this district more by absorption than by the weight and power of its seaward flow. The sewage of Paterson may almost be said not to have below Dundee dam at Passaic, the long stretch of sluggish stream at Dundee lake above the dam precipitating the solids by the mechanical process so generally used. From Passaic down the tide ebbs and flows, the volume of course depending upon the rainfall, but not developing into a continuous current at any time. We have not, therefore, a river which will carry away the deposit of sewage so as to scour its own banks and bottom. Its self purification, in short, depends chiefly upon there being sufficient dilution, and when the extreme limit of the water's absorbing capacity is reached we have a condition which is not so much that of an open sewer as of a cesspool. That the limit has been reached was demonstrated by the dry summer of 1895, and in that year, and at intervals during 1896 and 1897, when the rainfalls were interrupted, the recurrence of the cesspool features of the river was so immediate and so obvious that there could be no questioning the thorough establishment of the fact that the river has become incapable of assimilating additional sewage in its ordinary flow. The consequences are as inevitable as death.

Now, if we are right in assuming that the violation of the laws of health is something which must be checked as we would prevent crime or contagion, and that the Passaic river is an offence which imperils life and property, it seems obvious that creators of such condition should provide the means of removing it and that those who would share the benefit of the remedy should also share in the provision of it. The drainage district has heretofore carried its sewage to the river as a place of final deposit; that place having become dangerous, it is demanded that the rule which removes the cesspool from the city lot should apply to the cesspool which has been created by using the river as a place of sewage deposit. In planning to relieve the river, it was ascertained by the Commission that an arterial sewerage system extending from the Paterson Falls to Newark Bay, which would probably cost \$6,500,000 and have a length of nearly twenty-six miles, would accommodate the sewage flow of the population of the cities and towns of that drainage district. It was the compactness of the population which primarily led to the decision in favor of an arterial system. The collection, at one point, of the sewage of the towns and cities of the district was found to be necessary and it was believed that one great interceptor should perform the work for the whole district rather than that there should be several such to collect for parts of this concrete section. The decision was made less difficult by the failure to discover localities fitted for disposal of the sewage of Paterson and Passaic, and by the obstacles which would be encountered in using any place for such a purpose in a thickly settled district. The commission

ers were driven toward an arterial system, with eventual sea disposal below the populated places in the drainage district, and that simplified their work.

Now as to the final disposal. We have a community of half a million souls dependent upon the open river for an outlet for their sewage, and find the river overburdened, depositing its solids as it sluggishly makes its way to the sea, and sending on the contaminated waters to reach the ocean before restored to their pristine purity. We propose the collection of the sewage into a sewer which will relieve the river of its foulness, and we point out that a large part of the work contemplated is a pressing necessity through the absence of local interceptors. We reach the salt meadows between Newark and Elizabeth, opposite Newark Bay, and there the collection work for the Passaic river proper may be said to end. The discharge as recommended by our engineers is to be made into Newark Bay. The engineers suggest a flume a mile and nine-tenths in length, extending from the interceptor's terminus in Newark Bay at Great Island to a point in the bay at deep water. There the discharge is proposed to be made, under such conditions as subsequent developments and investigations may make advisable. Should a nuisance be created there a further extension of the sewer to a point on the lower Bay of New York is recommended by the engineers, but it is believed by them that such danger would be small. We are, however, met by opposition to the discharge at this point from places located on the bay and below it, and from various sources. It has been claimed that the prospective contamination of the Bay only transfers the nuisance to a point lower down the river and that large interests would be injuriously affected. I am not prepared to enter just now into a full defense of this, but I do assert that so far as concerns the collection of the Passaic River drainage district and its conduct to the point indicated, it is a demonstrated necessity, and that the further disposition can be made at no other point so well. It may be further asserted that the practicability of discharging at outgoing tides; of precipitation previous to any discharge; and of the development of still newer methods of treatment before finally releasing the fluids for sea disposal, offers recourses sufficient to meet the objections that have thus far been raised. Should a further extension of the sewer to the larger bodies of water in New York Bay be required, there are other districts which would find the route the best available for them, and thus the cost of extension would be somewhat reduced. It should be mentioned that the island in the salt meadows, indicated in the report as the place of final collection, is comparatively remote from population, and is surrounded by marshes which would prove a barrier to growth in that direction.

It is also to be noted that a sewerage system for South Orange, which will eventually include other places, fixes the place of deposit at the outlet which the engineers of the Commission designated for the main sewer. It is then established that for the lower Passaic sewerage district it is necessary to construct an arterial or trunk-sewer collecting the sewage of the district from the cities and towns now having sewer systems or soon to construct them, and that such trunk system should end for the present at Newark Bay. This is found not only by affirmative fact but by the absence of interceptors in the cities, by the absence of suitable disposal grounds available near the cities and by the objections raised by large suburban population occupying territory which might be made available, as well as by the necessity of providing an outlet for the fluids after disposal and by the superior facilities of the meadows opposite Newark Bay for collecting purposes. Let the final discharge be into lower New York Bay or Newark Bay, and the necessity of conveying sewage to the point indicated remains unassailable. And for the capacity of Newark Bay to receive and dispose of the estimated flow of 70,000,000 gallons daily we have the estimates of our engineers. The desirability of using mechanical precipitation before such discharge has been carefully considered, and the convenience of access for boats to convey the sludge to sea if necessary, is a further advantage of the locality. The difficulties of land disposal in those sections have led to movements favorable to a great extension of the arterial systems.

There are parts of five counties and eighteen or twenty cities, towns and hamlets in the lower Passaic sewerage district. Each has its own interests, purposes and municipal ambitions, and each has much to do and little money to spend. The work is necessarily of a State nature, requiring a broader and higher authority than that granted any of the local branches of government. On the other hand, the constitution of the State denies to the legislature the authority to provide for the payment of such a costly undertaking by the necessary issue of bonds. It is required, therefore, that substantially a new method of exercising the powers of the govern-

ment should be devised and to warrant such an innovation the necessity should be great. The imperative nature of the demand for the abatement of the Passaic nuisance has been demonstrated elsewhere, and the duty of the State to take action depends upon whether it be agreed by such students of sanitation as are now before us, that an injury to public health must be repaired not merely as a matter of policy but as a duty of government, similar to that of the prevention of crime and its punishment. Upon no other basis should we be willing to advocate measures which the limitations of constitution and existing forms of local government thrust upon the State for the correction of this and similar nuisances. The proposed law would briefly define that when a commission which has been duly appointed to consider the subject reports that any stream has been so befouled by sewage as to become a public nuisance and detrimental to health, the governor may appoint three able and discreet men with power to remedy the nuisance at once. The initiative is in the legislature so far as the preliminary examination is concerned. The governor acts, the commission proceeds with its task. It requires the selection of competent men and gives them very great powers in the raising and spending of money. The local authorities pay for the expense, but do not supervise the expenditures. The three commissioners are State officers, charged with a heavy responsibility, subject only to removal by the governor and to his scrutiny of their accounts. It is an exercise of power absolute, beyond the ordinary, and to which objection might justly be made if it were not founded upon that doctrine that sanitation is a higher law than that which controls the ordinary exercise of government in this State and country and justifies more pronounced measures.

It is the design of the statute as proposed, to meet other needs of the same kind in other parts of the State, and these may be expected in time. The sewerage problem is everywhere, in the remote farmhouse where the well may adjoin the cess-pool and the dairy which supplies the city milk may be tainted; in the suburban community desirous of city improvement at a rural rate of expense; in the city struggling to make its sewerage system equal the needs of its rapid growth and requirements of health, on and up to the questions which are involving the collection of sewage from the different municipalities of some great drainage district where the means of local disposal are not available. In our State it compels attention by the evils resulting from its neglect, and we deem ourselves fortunate that the costly problem is pressed upon the State for a solution. These difficulties we find are being encountered all over the country, in other States: In Massachusetts, where action of momentous value has been taken; in Connecticut, where it is now under investigation—wherever there are great cities, narrow rivers being polluted, and an intelligent body of sanitarians to attack the evil. We find it in London, Manchester, Glasgow, countless centers of population grappling with it and guessing their way. There is no established rule, and no all wise sanitarian or engineer. Shall we follow the processes of nature? We find her too prodigal for our small means. Shall we imitate older civilizations? Our conditions are different, and our changes more rapid. We must work out our own salvation as best we may. This should be done by educating the masses through organizations like this. It must ever be borne in mind that there is never a complete and final solution of all difficulty, and crowded communities must be taught that the cost of removing the refuse of the cities bears a large ratio to the cost of supplying such communities. What goes into a community must emerge in some form, and if the transformation reduces it in bulk, it has also made it more difficult to care for safely and healthfully. Kindly critics often referred the Commission to similar problems abroad, and found much to instruct therein, but the work of London, Berlin, etc., is at its best only progressive and as far from perfect as any other branch of human progress. The tax-payers here naturally fear the great increase in the cost of living, but the sound bodies and clear heads which have through invention lightened labor, and so vastly increased the earnings of humanity, may be considered more than an offset for the requirements of the modern sanitation, which not only reduces the death rate but adds to the comfort and efficiency of the living. The Lower Passaic River runs its slow course through one of the fairest valleys in America with a population which it owes to its advantages for residential purposes, and its nearness to the great metropolis. Under healthful conditions the limit of the growth of population can scarcely be defined. Without sanitary provisions, it would be doomed. Education has not merely taught the people to correct bad conditions; it has warned them what to avoid. If the Lower Passaic River has become a nuisance to the public by contamination from sewerage, instead of the attractive and useful stream it was a few years ago, then it

must be restored by removal of the wrong. A river which yields stenches which in the heated air of August sicken many and alarm all; from which the pollution has driven fish life; which has lost its charm as a public resort and the best of our parks; which is driving away population; which, in short, is assuming the conditions of a nuisance instead of a benefaction, compels remedial action. The legislature should act at once, and in time to prevent further injury to the large property interests involved. We can not trifle with such perils, we must regard the interests of the whole body of the people as superior to those of any individual or single community. The influence of this Sanitary Association will aid the project, not only for what would be accomplished for the Lower Passaic valley, but for the principles in government for the benefit of sanitation which a work of such a character would establish and perpetuate in our State.

(To be continued.)

SELECTIONS.

A Case of Tyrotoxicon Poisoning; the Bacteriology of Milk.—At Halifax, England, a case of ptomain poisoning, with a coroner's inquest, has occurred. It is commented upon as follows in the *London Lancet*: "Some interest attaches to an inquest recently held at Halifax on the body of a child, aged 4 years, who was put to bed on November 27, apparently in her usual health, but was taken ill about 7 o'clock the following morning and died in a few hours. A postmortem examination was made by the medical officer, who deposed that death was due to some poisoning the exact nature of which he was unable to specify. It was suggested that the girl might have sucked the coloring from a doll which she took to bed with her, but it was also further mentioned that she had partaken of some ice-cream which might have caused the symptoms. The coroner directed the borough analyst to make an analysis, and he expressed the opinion that the symptoms and postmortem examination pointed to poisoning by tyrotoxicon, a substance derived from unwholesome milk. He examined the ice-cream for tyrotoxicon but found none present. He gave some useful hints, however, that duly found their way into the press, namely, that this substance was destroyed by a temperature of 90 degrees C., and consequently if milk was boiled, should tyrotoxicon be present it would be destroyed. This adds another warning to the community at large against drinking milk that has not been boiled, and points the necessity that farmers and milk dealers should scald out the utensils in which they place milk."

We are reminded by the foregoing of a discussion of the milk supply question that recently took place in the Massachusetts Association of Boards of Health, in the course of which one of the speakers stated that in some places in Boston the milk storekeepers put rotten eggs, cheese, bad molasses and other refuse in the cans to be returned to the dairy. The practice of returning unclean cans and stoppers from the dealer to the producer was condemned. Before so returning them, the dealer should be required to see that they are thoroughly cleansed and sterilized by the use of steam or boiling water. "Inasmuch as milk is one of the best culture media for micro-organisms, and is always liable to become infected with the germs of disease, and further, inasmuch as the process of Pasteurization is known to destroy such organisms, it is recommended by a majority of the committee that, as far as possible, all milk be Pasteurized before it is sold."

In the course of this same discussion Dr. Sedgwick, the well-known bacteriologist of the Massachusetts State Board of Health, remarked that as for himself he now never drank a glass of raw milk. He advocates not only that all milk should be Pasteurized but that this should be done early. He said: "If you go and buy some milk that already has millions of bacteria in it, and a lot of dirt and all that, and Pasteurize that milk, you will undoubtedly have rather a hard time. Milk ought to be Pasteurized at the latest very soon after it is drawn from the cow, and then it would be much cleaner and better

taken care of, and when it is treated in that way it is almost perfect. I really believe the time is coming when it will be regarded as a *very unusual and uncivilized thing to drink unpasteurized milk*; and I think, if I had brought in some Pasteurized milk and passed it around here, and said nothing about it, nine out of ten of those present would not have known but they were drinking ordinary sweet milk, that is, most people, having had no sweet milk in their lives, have got used to a commercially sweet milk, and when they get hold of sweet milk they think something is the matter with it. But anybody who has ever squirted milk into his mouth from the teat of a cow, as all boys have done who live in the country, knows that milk that has been Pasteurized tastes like that he used to get when he was a boy, practically normal milk. I believe in cities especially we have got to come to that sort of thing; and I believe that unless we do come to that, we shall see cholera infantum and epidemics of typhoid from milk. I really believe if we could get Pasteurized milk into Boston today, and let nothing else go into the tenement-house districts, the number of cases of cholera infantum we should have would be too trifling to mention. And the moral of all this is that boards of health will not be considered to have done their full duty in respect of the protection of the milk supply if they stop short at their usual chemist analysis.

"I believe that the time will come when every well regulated local board of health will have some one at its laboratory, I mean in every city of any size or large towns, who should make an examination of milk that is sold, not only in respect to the amount of water that it contains, that being probably the least damaging of all things, but in respect to dirt and its age or staleness, and that in such examinations counting the numbers of bacteria and determining the acidity will be of very great value." The remarks of Mr. Nathan Straus, the newly appointed president of the New York City Board of Health, may be put on record in this connection. He says: "There is practically no milk delivered for general consumption in cities that is fit to be fed in its natural state to young children. I think I have fairly demonstrated the proposition that many thousands of infants' lives are annually sacrificed by the neglect to supply for the nutriment of children milk which has been sterilized. I hold that neglect to be criminal." The ice has been broken. We may expect soon to hear that the multitudinous institutions throughout the country for the care of children, have found their account in the abandonment of raw or unpasteurized milk, unless it have the certificate of a bacteriologist.

Thyroid Medication in Diabetes.—The principal feature of thyroid medication is the acceleration of tissue nutrition with the habitual predominance of denutrition. To this is due its effect on obesity. It is accompanied occasionally by a slight glycosuria, amounting in Ewald's case to permanent diabetes. In Georgiewsky's experiments with dogs this glycosuria did not appear when the thyroid was administered in combination with a meat diet, but only when the dogs were fed with soups. He also states the fact that the days when there was sugar in the urine there were less unoxidized substances than on other days, showing that the glycosuria can not be attributed to any lack of oxidating energy. Von Noorden asserts that the internal secretion of the thyroid prevents the formation of fat at the expense of the sugar; in other words, it interferes with one of the mechanisms that regulate the glycohemias, which ingenious hypothesis deserves to be verified. This fact that thyroid medication and hyperthyroidization favor the production of glycosuria renders especially remarkable the case reported by Branthomme of an arthritic diabetic improved by the ingestion of thyroid tablets, until now, a year later, there is no sugar in the urine, and merely traces of albumin. Lépine comments upon this case, remarking that if diabetes results from deficient nutrition, then thyroid medication accelerating tissue nutrition would affect it favorably, similarly to the beneficial effect attained in diabetes by d'Arsonval and Charrin with high frequency currents. De Renzi and Reale, on the other hand, have noted glycosuria follow the use of these currents, showing again the analogy between them and thyroid medication. Both accelerate tissue nutrition and thus might improve a diabetic, but more frequently they are injurious, as they stimulate denutrition to such an extent. Lépine concludes by reporting the case of an obese diabetic he is treating with the thyroid medication. At first the sugar was increased, but in a few days it began to show a constant decrease. Intercurrent erysipelas interrupted the treatment, which he intends to resume later.—*Semaine Méd.*, December 22.

PRACTICAL NOTES.

Injections of Artificial Serum for feeble new-born infants have been found remarkably beneficial by Loviot. *Presse Méd.*, January 22.

Powder for Varicose Ulcers of the Leg.—Finely pulverized sodium chlorid, 50 grams; pulverized menthol, 5 grams. Mix and pulverize (Simonelli, *Journ. de Med. de P.*, January 9).

For Stings of Insects.—Jacquet proposes the following: Naphthol 10 parts; menthol 1 part; ether q.s; petrolatum, q.s. to make 100 parts. Dissolve the naphthol in ether, add the menthol and finally incorporate the solution with the petrolatum. —*N. O. Med. and Surg. Jour.*

An Ointment for Pruritus.—The *Jour. de Med. de Paris* attributes the following formula to Coover: Yellow oxid of mercury, 1 part; vaselin, 200 parts. The ointment should be applied at bedtime, and also, if necessary, in the morning, by firm and prolonged friction, the affected parts having been previously washed with warm water and soap.

The Lithotomy Position in Partu. O. Schmidt of Moscow recommends this position whenever the head is engaged in the pelvic cavity or outlet; as the labor pain ceases the feet are replaced on the bed. The increased intra-abdominal pressure and the enlarged pelvic outlet render the birth easier in this position, and it proceeds with remarkable rapidity. —*Cbl. f. Gyn.*, 1897, No. 47.

Gravity of Generalized Pruritus in Pregnancy.—Whenever there is general pruritus sufficient to cause insomnia, the subject is evidently affected with a serious auto-infection. In every case observed by Pinard and Lutaud the pregnancy was not normal; either the fetus died or there was eclampsia, or defective insertion of the placenta. The combination of bromid and chloral seems the best medication, although the immediate termination of the pregnancy has been suggested. —*Journ. de Méd. de P.*, January 16.

Girdle for Sea Sickness. Galliano of Turin is now patenting a compressing girdle or belt which he claims has absolutely prevented sea sickness even in those most easily affected. It exerts a strong pressure on the gastric region from both front and rear, which has long been known to have a favorable effect in threatening sea sickness, although no special appliance for the purpose has ever been devised before. —*Gaz. d. Osp. e d. Clin.*, January 23.

Orthoform Anesthesia.—Orthoform does not produce anesthesia on sound skin or mucosa, only on open wounds. Hirschbrück recommends the injection of a 3 per cent. mixture of orthoform and water, with which he has obtained excellent results. He precedes it with 0.002 cocain mur. to prevent pain from the injection. The anesthesia thus produced is lasting and the absolute non-toxicity of orthoform adapts it to many of the minor operations. —*Berl. klin. Woch.*, 1897, No. 49.

Maltent's Method of Treating Spina Bifida.—After incision parallel to the axis of the spine, and isolation of the sac, a small quantity of the liquid is evacuated and the tiny hole closed with hemostatic forceps, twisted a little to form a small pedicle below them. This pedicle is then ligated with catgut; the part between the ligature and the forceps resected, and a small compressing bandage applied. The next day the operation is repeated exactly the same, on the opposite side of the sac, avoiding the nerve elements, and so on gradually until scarcely anything is left of the sac, which is finally reduced at last, unless this has occurred spontaneously. The whole is concluded with a Senenko osteoplastic operation, and suture in three planes. —*Gaz. degli Osp. e d. Clin.*, January 23.

Citric Acid in the Prophylaxis of Whooping Cough.—Moncorvo Filho of Rio Janeiro states that the special bacillus of pertussis is destroyed in its chosen home, the larynx, by swabbing

the periglottic region with a 10 per cent. solution of citric acid, with simple syrup. It also constitutes an effective prophylaxis against infection. He succeeded in preventing the disease in many children living with others infected, by this means, or merely the administration of small quantities of citric lemonade during the day. He considers resorcin and asapol the most effective of other remedies. —*Brazil Médico*, December 22. A long article by Gillet in the *Presse Méd.*, January 22, recommends belladonna in progressively large doses as a simple and valuable symptomatic in whooping cough.

Treatment of Mental Strain.—In cases impossible to treat by the only rational means, removing the cause, in which the mental strain must be kept up, Romme recommends in addition to hydrotherapy and massage, two pills of 1 milligram strychnin arseniate each, and one pill of 8 milligrams zinc phosphid during the day, at breakfast or dinner according as the person retires early or late. This can be kept up during the entire period of intellectual work, suspending it two days each week. If the strain is continuous, the pill can be taken from time to time whenever especially fatigued, or a strychnin pill every other day and a zinc pill every fourth day. Make the latter according to the formula: zinc phosphid, 0.80 centigrams; pulv. gum arabic, 1 gram; pulv. licorice, 3 grams; honey q.s. to make 100 pills. Coat with silver and keep dry, sheltered from the light. Renew every month. —*Presse Méd.*

The Improved Technique in Trephining now possible with Gigli's wire saw is the subject of an article by E. Braatz in the *Cbl. f. Chir.* for January 22. He states that it avoids all jar, and the piece cut out fits in again with remarkable precision. The edges can be cut straight or slanting as desired. He has invented an instrument to drill the preliminary holes on the principle of an augur, but very short, 15 cm. the total length, which ensures great delicacy and accuracy. The U-shaped part usually grasped by the hand is made too narrow to admit the hand. A projecting handle rides loose upon it at right angles to the shaft, and by this the drill is turned, while the pressure is from the other hand above. He uses an ordinary drill changing to a fraise as the bone is nearly penetrated. He inserts the saw with a sound curved to correspond to the distance between the holes; 93 degrees of an arc of 8 cm. diameter for a distance of 4 cm.; 140 degrees of an arc of 5.3 cm. for a distance of 3 cm. and a half circle 2.5 cm. in diameter for a distance of 2 cm. The drill holes serve for drainage afterward. *Vide JOURNAL*, Vol. xxix, page 504. Gigli is pronounced Jeel-ye.

Methyl-Blue in Malaria.—J. P. Cardamatis of Athens reports that he has administered methyl blue in 275 cases of malarial fever during the last three years, and has been amazed at its prompt and effective action. He considers its therapeutic value in malarial fever far superior to that of quinin and "can not praise it enough." Its efficacy was especially noticeable in persons so saturated with quinin that they had ceased to react, and in those in which quinin was counterindicated. The results were undeniably successful in 93 per cent. of the total cases of acute and chronic malarial fever treated, and it even confers immunity; only 15 per cent. of the persons continuing to live in extremely malarial districts had relapses within a year. The result was negative in 7 per cent. The only inconveniences were the staining of the mouth and clothing when the liquid form was used (infants). He gives four tablets a day, one every two hours. The daily dose for adults is 10 to 12 grains; for older children 8 grains, for younger children 6 grains, infants 1 to 2 grains. It is administered ten to fifteen days and then suspended for two or three days and a purgative given, resuming for three or four and then suspending for three to eight days and resumed at intervals, ensuring a total of seventeen days in twenty-two for acute or chronic quotidian, in which the fever disappears in the first five days, sixteen days in forty-eight when the fever reappears in the first five days and twenty-eight in sixty days in the tertian and quaternian form. —*Deutsche Med. Woch.*, February 3.

THE

Journal of the American Medical Association

PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

Per Annum, in Advance	\$5.00
Foreign Postage	1.75
Single Copies	10 Cents.

In requesting change of address, give *old* as well as new location.
Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, 100 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the *Editor*, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, MARCH 5, 1898.

APYRETIC TYPHOID FEVER.

It is an interesting fact in clinical medicine that every infectious disease which attacks human beings in the vast majority of cases results in producing a more or less constant rise in bodily temperature. One would suppose that the poisons of one infection might irritate the heat centers in such a way as to cause an increased generation of heat, while other poisons would depress them to such an extent, or would so seriously interfere with oxidation processes in the body, that instead of the temperature rising above normal it would fall below it. It is true that in a certain number of cases where the infection is particularly malignant, and where the individual seems peculiarly susceptible, fall of temperature does follow the infection, the patient immediately passing into a condition of profound toxemia with symptoms resembling collapse, but these instances are so rare as to be practically curiosities in medical literature. It is interesting to note, therefore, that from time to time, as our observation of diseases becomes more accurate and our methods of diagnosis more complete, physicians are recording instances in which grave infectious diseases have been attended, if not by a fall in temperature, at least by no pyrexia. Originally, fever was perhaps the most important diagnostic point in connection with the case, but at the present time we regard it merely as a symptom of some prominence, possessing certain indications, and rely upon other physical signs more objective in character before we make a positive diagnosis.

Many years ago a very large number of cases of true typhoid fever were not recognized as such and

were classified under the head of gastric fever, or simple continued fever. These cases are today properly recognized and add very largely to the number of cases of typhoid fever which are reported. Some years ago FISK of Denver, reported a series of cases of typhoid fever, in which the temperature ran a typical but nevertheless apyrexial course, and similar instances have been seen in the East, recorded by clinicians, though none of them so far as we are aware have reported them as thoroughly as has Dr. FISK. In this connection it is interesting to note a recent paper by WEILL and PEARY, published in *La Province Médicale* for November, 1897. In this case the temperature was normal or subnormal, practically throughout the entire course of the disease, but the pathologic process was accompanied by the characteristic symptoms of typhoid fever so undoubtedly that no question as to the diagnosis could be admitted. The symptoms began with the usual vague manifestations of general wretchedness, with great fatigue upon attempting any exertion. There was loss of appetite, frontal headache, restless sleep, vertigo, nausea, but there was no epistaxis. There was also pain throughout the limbs. The tongue was characteristic, red on the edges and rough in the center. Constipation was present. There were no rose spots early in the attack. The abdominal walls were soft and pliable. The lungs were normal, there was a slight murmur at the base of the heart. The pulse was quick and small and easily accelerated by excitement. Vomiting was sometimes present, and a restless sleep finally became complete insomnia. Several days later in the case abundant epistaxis came on in the night. There was diarrhea of a non-fetid character, which was persistent and vomiting became a persistent symptom.

WEILL and PEARY go over the case very carefully, present its temperature chart, exclude anemia and other causes of low fever and conclude that this was another instance of apyretic typhoid.

QUANTITATIVE HEREDITY.

The usual views of hereditary transmission of qualities from parent to child have been contentedly vague as to the exact amount derived from either parent or grandparent or more remote ancestor. It has been probably assumed by most of those who have given any thought to the subject that such calculations were impossible or that at least that the laws governing such transmission depended upon so many and so different conditions as yet, and probably long to be, unknown to us, that it was useless to try to seek them out. We know as physicians that certain pathologic heredities are more or less special to one or the other sex, that in some prominent instances a feature or cast of countenance, mental or moral trait seem to be a family characteristic, while in others there is apparently nothing to indicate descent

in the way of family traits or features. Once in a while a known ancestral character makes its appearance, having skipped one or more generations, and to this we give the name of atavism and leave further explanation as useless or impracticable. The hitherto recognized laws of heredity are few and hardly touch the question on its quantitative side; the distribution of ancestral traits has been considered to be too capricious as a rule to afford the data for generalizations in this particular direction, at least in the human species, where all matters involving faculty or capacity are so much more complex than in the lower animals.

Several years ago Mr. FRANCIS GALTON, one of the most active investigators of this subject, published a theory of heredity that takes account especially of the respective portion due to each parent and ancestor. Counting the total of the organism as 100, he held that one-half, or 50 per cent., is derived from the progenitors, one-half of this from each parent. They in turn derive half their traits and features from their respective parents, and so on to the most distant ancestral relative. Any individual may therefore be reckoned as owing one-quarter of his peculiarities to each of his parents, and through them one-sixteenth to each of his four grandparents, one-sixty-fourth to each of his eight great-grandparents, and so on in a continually decreasing ratio to his remotest forefathers. In a more recent publication GALTON has given facts confirming this theory which were derived from a study of a well-known breed of dogs showing certain markings and peculiarities that facilitated this particular line of inquiry, and it may perhaps be accepted as a fairly probable working hypothesis.

What is true of the lower animals is also within certain limits applicable to the higher ones and from this point of view GALTON'S theory is of interest to us as physicians. It will help us to a provisional estimate at least of the possibilities and dangers of intermarriage, of the risks of inherited disease, etc. One consideration, however, must not be overlooked; it must not be assumed, to use a somewhat vulgar comparison, that the cards are thoroughly shuffled at each re-deal, that the transmission of qualities is general rather than special in every individual case. The inheritance transmitted from parent to child may be in large part that which the former received from his ancestor; this is the basal fact of evolution and of the perpetuation of species as well. We see it in the family features transmitted through many generations, of which the Hapsburg lip and the Bourbon nose are historic examples. This fact, however, is perfectly compatible with GALTON'S theory of heredity, though it would probably so complicate the observations that it might sometimes make it the more difficult of confirmation in carrying out the investigation in the higher animals and especially in

applying the theory to the heredity of human faculties and traits. It would be of especial interest could we also find some law that governs the apparently so capricious selection of qualities in inheritance, irrespective of the amount derived from either parent, but that is a problem for the future.

GALTON'S theory, if it is capable of being sufficiently demonstrated as a fact, is certainly a valuable addition to our resources for the study of heredity, not only in a general scientific point of view, but also in all appearance and probability in its special application to the facts of hereditary disease.

MALARIAL INFECTION.

Perhaps one of the most remarkable facts presenting itself to the student of medical literature, is the swing of the pendulum, as it may be called, upon almost every topic pertaining to the science. This seems to be especially true concerning those subjects of which we seemed or seem to have more than an average knowledge. Histories of medicine teem with examples. The controversies of pathologists as to the formation of infarcts, the etiology of tumors, the changes taking place in inflammatory processes are familiar instances.

To discuss a subject of somewhat more recent date: if there were one disease upon which we could place our scientific finger and say, "It is," or "It is not," that disease is malarial fever. The intermittents were reveled in by our laboratory savants as mere child's play, while every dabster at the microscope was surprised and delighted at the fields of tertian and quartan organisms so easily outlined before him. So we thought. But while burying ourselves in the laboratory, carefully and accurately examining the blood of all patients (not those alone suspected of being malaria infected), always finding, if not at first, after repeated examinations, the specific hematozoon of our search, the clinician has been directing his attention into other lines and after a few cursory peeps through the microscope he exclaims, "Behold, I do not see this much-lauded insect: ergo, it is not here. I have made the diagnosis of my patient's trouble by his chills, fever and sweats, his enlarged spleen, and has he not a labial herpes? The clinician has been under the heel of the pathologist and the bacteriologist too long. I will hie me to my den and there indite an epistle entitled, '*Malaria sans Plasmodia*.'"

In 1881 the researches of LAYERAN gave to the world the statement that malaria was another of the class of infectious diseases; a disease in which the specific organisms were found within the red corpuscles of the blood and upon which they exerted a parasitic action, growing at the expense of their hosts. A new impetus was given to the study of malaria, and incidentally to the blood, and it was soon developed that

the plasmodium, as the organism was called, was found in no other disease. Italian observers, CELLI, GOLGI, MARCHIAFAVA; Prof. KLEBS, and in this country, PEPPER, OSLER, DOCK and others contributed to place the affection upon a firm scientific basis. Three distinct varieties were discovered, the tertian, the quartan and the estivo-autumnal, the difference being in the length of maturation, the size of the different varieties and certain pigmentary changes. One of the most valuable discoveries of recent years has been the pathognomonic sign of the estivo-autumnal, the presence of crescents and ovoids in the blood after the first week. Experts all recognize that almost invariably obscure malarial symptoms occur in this form. The not unusual enormous difficulty in finding the parasite of this variety will be appreciated by all who have had any experience in this kind of blood work. The less direct the symptoms pointing to malaria, the more difficulty is encountered, as a rule, in finding the parasite. All are familiar with the presence of solitary "malarial" (?) symptoms, headache, neuralgia, chilly sensations, perhaps coming on with some approach to periodicity. Think how comparatively few are the plasmodia requisite to produce such a condition, and then turn your mind to the fact that an exceedingly small proportion of this diminution is found in the peripheral blood. Is it any wonder then that even with the best observers and most careful and long-continued searches cases occasionally occur that are barren of results as far as the hematozoon is concerned?

The dictum of THAYER and HEWETSON that the crescent positively indicates estivo-autumnal malaria, was followed by that of OSLER, than whom no one is more qualified to judge, that malaria is always due to the plasmodium, and secondly, that any fever that resisted the action of quinin, always of course properly administered, is not malaria. As the scientific aspect of this disease became more and more worked out, and not every case in which no diagnosis could be made was labeled "a touch of the malaria," that *bête noire* of every true physician, this latter statement has become a recognized law of therapeutics.

Scientifically, in what way is the fever of malaria produced? In the intermittents, by the reaction on the part of the system against the maturation and invasion of an immense number of parasites during a comparatively short space of time. In the remittents, other cycles of growth are completed before the reaction from an immediately preceding cycle has been recovered from. In the continued forms, sporulation and invasion by a small number of parasites is of constant occurrence, but as the number is small the reaction on the part of the economy is not great; hence there are no chills and the fever is comparatively low.

Experiments outside the body have repeatedly demonstrated that the parasite perishes in a weak

solution of quinin, as dilute as 1 to 10,000. If absorbed, 0.3 gram of quinin would make of the humoral fluid a solution of several times this strength. The first indication then to be filled in the treatment of malaria is to be sure that our antiperiodic is administered in a form capable of assimilation by the case at hand. This of course entails in not a few instances a consideration of the stomach mucosa. If we administer a drug, which by its presence in the blood results in death to the malarial parasite (if outside the body, why not within?) it naturally follows that non-assimilation will result in non-cure. Would not atrophy of the gastric mucosa result in diminished or non-assimilation of our quinin? In malaria infected districts the inhabitants, whether suffering from the disease or not, are accustomed to take large doses of quinin more or less regularly, and more regularly immense doses of whisky to ward off a possible infection. In reviewing the etiology of atrophic gastritis, what more constant or more potent factor is present than the ingestion of alcohol. Another point: In the West and Southwest especially quinin is not always administered by a regularly qualified physician. The people themselves know the danger that lurks constantly around them and are always drugging themselves for every ailment of all forms and descriptions as "a touch of the malaria." Very good. Now as to the preparation: The bisulphate of quinin in solution? No indeed. What need when the drug companies turn out yearly millions of their little 0.3 gram pills. Now we have coming together these medical bullets and a mucosa, gastric and intestinal, practically useless for purposes of assimilation. It is curious that an occasional case is not reported of intestinal obstruction due to undissolved quinin pills. The practical result that concerns us, however, is that these chronic cases, always estivo-autumnal, by far the hardest to cure, continue to have fever, and we are where we started. The patient has malaria beyond a doubt; he has been saturated with quinin and his fever is still flourishing in a quiet way. Therefore, the statement "that any fever which will not respond to quinin is not malaria," is false. *Q. E. D.* Make sure of one little point, that your quinin has come in contact with the blood stream, and the case is yours. This is not a story of invention. The writer has himself experienced such cases. The thought occurred to him, "Has my quinin been absorbed?" to be immediately followed by the second, "how to be sure that in any given case it is absorbed." Hypodermic injection! The experiment was tried and the battle was with the dictum of Prof. OSLER. This law was laid down five years ago and thousands of physicians all over the land are ready to vouch for its truth. Those of you who are not, examine the blood repeatedly; see if something else will not account for your "touch of malaria," or give hypodermic injections; 0.3 gram of a solution of the bisulphate injected

every four hours in the deep muscles of the back or in the gluteal region, will transfer your patient's blood into a weak quinin solution, in which death of the parasites will occur as fast they are set free in the blood. The pain is no greater than in the giving of any other hypodermic injection, abscesses are no more common, and you are sure that your drug will be taken into the general system.

The burden of all this is that in a recent number of a large eastern medical journal, a lengthy article was published on malaria, which coming from a man of considerable clinical experience, might tend to weaken in the minds of many men who perhaps have now had the best of luck in finding the plasmodium, the real standing of this organism as regards ague infection. To these let it be said that if we know anything of infectious diseases, we know that a specific micro-organism is always the cause of the given disease; that it never enters as a causal relation into any other infectious disease.

The article in question takes the stand that the finding of the plasmodium is by no means essential in the diagnosis of malaria. In the classic intermittents, where the cycle of chill, fever and sweat come on at the same time daily, every other day, or every fourth day, that is of course true; the veriest tyro in medicine would without hesitation make the diagnosis correctly in such instances. And it is in these very cases that the finding of the plasmodium is attended with no difficulty. It is in the cases with obscure symptoms, those as mentioned before, that are due usually to infection by the estivo-autumnal parasite, that the diagnosis both clinically and microscopically becomes a matter of doubt. An affirmative therapeutic test in these obscure cases is not sufficient evidence on which to base a diagnosis. Many affections get well of themselves; quinin is often given as a tonic or as a placebo. Would we call all affections that improved or recovered because they happened to be receiving quinin at the time, indeed often in spite of it, of malarial origin?

The distinguished author brings in support of his arguments, that while in pulmonary tuberculosis the finding of the tubercle bacillus in the sputum is of the highest importance, it is by no means of absolute necessity in making the diagnosis; the physical signs will almost invariably be sufficient. Very true, but what physical signs or even symptoms, barring one or two of the latter which might well belong to one or another of a dozen different diseases, do we have in malaria? To make a diagnosis of ague we must in many cases rely entirely on the microscopic examination. We all admit, in cases of pulmonary tuberculosis, the invariable presence in the lungs of the tubercle bacillus, even if we do not find the latter in the sputum. Why not give the plasmodium an equal chance as regards the blood. Some cases of

early tuberculosis have no cough or expectoration; hence the sputum is not always accessible for examination. The same can not be pleaded for the blood; it can always be obtained readily. Let not the pendulum swing us again into doubt and obscurity. Let us look upon malaria as an infectious disease, and keeping in mind the nature of this class, allow no one to make his boasts of his great successes in treating "a touch of malaria" without the innocent query, "Did you find the plasmodium in the blood, doctor?"

CONCERNING TUBERCULOUS AORTITIS.

The early opinion that the internal coat of the larger blood vessels of man is immune against tuberculous disease has been abandoned since the well known researches of WEIGERT¹ concerning the origin of general miliary tuberculosis from tuberculous foci in the walls of pulmonary and other veins. It is now generally known that in tuberculous leptomenigitis, for instance, there occurs a marked tuberculous disease of the small arteries.

When the walls of the blood vessels, particularly the larger branches, become tuberculous, then it is due, in the majority of cases, to direct extension of the process from a tuberculous focus in the vicinity of the wall. Independent tuberculous disease of the vessel wall is much rarer; in the majority of the cases it must then be regarded as of hematogenous origin. In the later stages, however, of such foci it is usually impossible to say whether the disease began in the form of a primary tubercle of the intima, that originated from deposition of tubercle bacilli in the blood stream, or whether the disease began as the result of a hematogenous tubercular infection of the vasa vasorum. Examples of both methods of origin have been described quite frequently in the literature.

The veins are much oftener involved in tuberculous disease than are the arteries. Numerous observations of venous tuberculosis, but only a small number of cases of tuberculous disease of the large arteries have been described. In the large branches of the pulmonary arteries MUEGGE,² WEIGERT³ and HERXHEIMER⁴ saw tuberculous proliferations projecting into the lumen, which undoubtedly were due to extension from the tuberculous bronchial glands.

Tuberculous proliferations in the aorta belong to the rarer diseases. DITTRICH,⁵ KAMEN⁶ and SIG⁷ have described the extension of tuberculosis from bronchial or posterior mediastinal glands, or from a cavity in the lung, to the aorta, with the production of aneurysm or rupture of that vessel.

Of independent tuberculous disease of the wall of the aorta, not due to extension, there are only a very

⁴ Virch. Arch., cvii.

⁵ Zeitschr. f. Heilk., ix.

⁶ Ziegler's Beiträge, xvii.

⁷ Inauguration Dissert., 1896.

few cases. ZAHN⁸ describes a case of multiple nodules in the aorta and the iliac arteries in a tuberculous individual with general miliary tuberculosis. While the exact nature of this case, which occurred before the time of discovery of the tubercle bacillus, has not been established, there seems no doubt but that it concerned a tuberculous proliferation. At any rate, that is the view which STROEBE⁹ has of the case. WEIGERT⁵ has also described tubercles in the aorta, and refers to some similar findings of MARCHAND and HEUBER. MARCHAND¹⁰ states that sometimes in miliary tuberculosis one can find small tuberculous caseous nodules on the intima of the aorta, which seem frequently directly due to the implantation from the blood stream. These nodules are, therefore, very much like the tubercles not so very rarely observed upon the endocardium in miliary tuberculosis. HANOT and LEVI¹¹ saw a larger tuberculous mass, with bacilli and giant cells, underneath the endothelium of the intima of the thoracic aorta in a man 61 years old, who died from miliary tuberculosis.

Very recently STROEBE has described an observation made on the body of a young man 16 years of age, who died from miliary tuberculosis, which apparently originated in the bronchial glands. There were very numerous miliary and larger tuberculous nodules in almost all of the organs. The heart was normal. In the ascending aorta, 2 cm., above the sinus of Valsalva, there was a small projection about one-third of an inch in height, which was firmly adherent to the wall of the aorta and covered with some fibrin. Otherwise the aorta was normal, and there were no apparent changes around the outside of the aorta at that point. Microscopically it was found that this nodule consisted of proliferated endothelial cells, with leucocytic accumulation, caseation in places, and fibrinous deposits upon the surfaces. There were no giant cells. The free surface of the nodule had undergone caseation in one or two places. In one place the elastic lamina had been destroyed, and the cells rested directly upon the media. Below the nodule the elastic tissue of the aorta was found to be somewhat loosened and split up. Otherwise the wall of the aorta was normal. The examination of the specimen for tubercle bacilli showed that these were very numerous.

In this case it does not concern a simple miliary tubercle but a larger mass, which in all probability originated as a miliary intimal tubercle. The case very much resembles the one already referred to, which was described by ZAHN as endarteritis verrucosa, inasmuch as it here also concerns an absolutely healthy aorta, without any tuberculous foci, without any disease in the immediate vicinity, and therefore a condition that must be regarded as an independent

tuberculous aortitis which developed upon a previously healthy wall. This is interesting because many authors, as for instance MARCHAND, deny the existence of an independent acute verrucose aortitis, of any etiology, corresponding to this usual form of endocarditis. Tuberculous aortitis, as described in this case, may be placed parallel with the cases of valvular endocarditis that occur in phthisic patients. Such endocarditis may occur upon previously healthy valves, as well as upon those previously diseased. The essential change in this aortitis consists in a proliferation of the endothelium, due to the action of the tubercle bacillus: the mode of infection with tubercle bacilli in this case may be reduced to two possibilities. Either the tubercle bacilli were implanted upon the wall of the aorta from the blood stream, or they were brought to the intima by the vasa vasorum in the subintimal layer of connective tissue. Perhaps the first possibility is the more likely one, because a large mass of tubercle bacilli in pure culture was found directly upon the place where the healthy endothelium formerly existed. It is also to be remembered that in the thoracic aorta the loops of the vasa vasorum do not reach entirely to the endothelium, but only to the border of the middle and inner thirds of the media, so that the inner third of the media is avascular under normal conditions.

THE WEEK IN CONGRESS.

Last week in Congress there were hearings by the Committee on Interstate and Foreign Commerce, of which Mr. W. P. HEPBURN of Iowa is Chairman. Dr. U. O. B. WINGATE, Chairman of the AMERICAN MEDICAL ASSOCIATION COMMITTEE and Secretary of the Wisconsin State Board of Health, appeared in favor of the SPOONER Bill, as did also Dr. H. B. HORLBECK of Charleston, S. C., Health Officer of that city, and Dr. A. H. DOTY, Health Officer of the City of New York. On the other side appeared the Chief of the Marine-Hospital Service, with some officers, and Dr. DRAKE, a railroad surgeon of Atlanta.

Dr. HORLBECK made the principal speech against the CAFFERY-HEPBURN Bill, and in favor of the SPOONER Bill. The points were such as have been summarized in the account of the Mobile meeting, and were sound and well taken. Congressman MAHON of Pennsylvania also appeared before the Committee in favor of his Bill, which is the one for dividing the country up into sanitary districts, each district to be presided over by a commission. He changed his original Bill so that it would be practically under the control of the Marine-Hospital Service.

In addition to an excellent argument on this question, Dr. DOTY presented a telegram showing that the New York Academy of Medicine had endorsed the SPOONER Bill. It should be remembered that the CAFFERY Bill was introduced in the House by Mr.

⁸ Virch. Arch., lxxxviii.

⁹ Centrbl. f. Path., viii, 1898.

¹⁰ Eulenburg's cyclopaedia, ii.

¹¹ Gaz. méd. de Paris, 1895.

HEPBURN, and is known as H. R. 4363. This Bill should be killed. The SPOONER Bill was introduced in the House by Mr. OTJEN, and is known as H. R. 8280. The earnest and active support of every member of the ASSOCIATION who favors the creation of a Commission of Public Health, is imperative. Write to your Member of Congress and Senator immediately, if you have not already done so, urging them to oppose the CAFFERY Bill and favor the SPOONER Bill, which is the bill prepared by the Committee of the ASSOCIATION, endorsed by the American Public Health Association and recommended by sanitarians everywhere, with one or two exceptions. These exceptions are, so far as we are aware, certain publishing organs that have books for sale, and a certain sanitary journal, the editor of which long ago survived his usefulness, and is more an object of pity than of any other sentiment. In some of these interesting articles a fling is taken at the Mobile Convention, because, forsooth, the plans of the bureau at Washington were not endorsed by that Convention. It is stated that the Convention was improperly influenced by gentlemen who were not in the interests of this autocratic bureau. Let us see. The bureau sent two surgeons, one passed assistant surgeon and one assistant surgeon, at public expense to attend this meeting, one surgeon being already on the ground as a resident. Every effort was made to bring the individual members of the Convention to suit the views of the bureau, and a great deal of energetic but misdirected effort to that end was made. That they failed is a matter of history, and now because of that failure the Mobile Convention is "of no particular consequence anyhow." The surgeon who acts as the Chief of the Bureau of Publicity and Promotion for the Marine-Hospital Service will have to write more editorials before he succeeds in convincing the people of the United States that the Mobile Convention was composed of any others than gentlemen who were not only in earnest in the cause they advocated, but were guided by the most patriotic sentiments.

Dr. SAUNDERS deserves great credit for his public spirit and the success of the Convention.

CORRESPONDENCE.

Against the Gallinger Bill.

THE DENVER AND ARAPAHOE MEDICAL SOCIETY,
DENVER, COLO., Feb. 3, 1898.

E. Stuver, M.D. There is a bill now before the United States Senate, action upon which may be had at any time, the provisions of which are inimical to the interests of the medical profession, and to many commercial interests. It is Senate Bill 1063, Calendar No. 136, entitled "A Bill for the further Prevention of Cruelty to Animals in the District of Columbia." In accordance with the usual custom, the bill was referred to the Committee on the District of Columbia, and favorable action thereupon was unanimously recommended by said committee. On Dec. 15, 1897, Senator Gallinger, according to the *Congressional Record*, announced his intention to bring said

bill before the Senate for discussion and action. It would, therefore, appear that action upon it may be expected at any time.

This bill, as is well known, is intended to control and restrict the practice of animal experimentation in the District of Columbia. Its principal supporters are the antivivisectionists. All of the principal National, State, and local medical and scientific societies have already protested against the proposed legislation.

At a meeting of the Denver and Arapahoe Medical Society, held at the Brown Palace Hotel, Jan. 25, 1898, the following resolution was unanimously adopted:

"*Resolved*, That it is the spirit of the medical profession of Denver that a strong protest be made against the passage of Senate Bill 1063, Calendar No. 136, entitled 'A Bill for the further Prevention of Cruelty to Animals in the District of Columbia,' and

"*Resolved, further*, That the President and Secretary of the Society be directed to communicate at once with our honorable Senators urging them to do all in their power to defeat a bill that will do untold injury to the advancement of medical science and to the prevention of disease among mankind and animals."

A committee was also appointed to attend the Stock-Growers' Convention, then in session in this city, with the purpose of interesting them in the defeat of the bill. They met with the most courteous reception, and easily succeeded in securing the passage of appropriate resolutions, a copy of which is herewith enclosed.

It has occurred to some of us that as the protests from medical and scientific societies are already practically unanimous, that next to their renewal, our best move is to interest commercial enterprises, such as the stock-growing interests. If it can be shown to the satisfaction of our Senators and Representatives in Congress, that the opposition to the bill is not confined to a certain clique of professional men, whose opposition thereto might be misinterpreted, but that commercial interests will also be affected by such legislation, their active co-operation for the defeat of the bill will be thereby secured.

Knowing your prominence in Wyoming and your large influence with the varied interests there represented, I write to you to enlist your active co-operation. It is desirable, first, that your Senators be written to, protesting strongly against the proposed legislation. Personal letters will probably be of most value. Protests from medical and scientific societies should also be renewed. In writing, give the number and title of the bill, as above. In addition to this, if you can get the stock-growers and agricultural societies, and such other interests as in your judgment are affected by the bill, to forward official protests, and if you can prevail upon prominent stockmen, who know the Senators personally, to write them personal letters, showing in what way such legislation would be detrimental to their interests, it is my opinion that much good may thereby be done.

I believe our best arguments, from a practical standpoint, consist in showing what great good has been accomplished by the investigations of the Bureau of Animal Industry of the Agricultural Department, in investigating diseases of animals, of ascertaining methods of early diagnosis, for instance, the tuberculin diagnosis of tuberculosis, and in providing remedies therefor, as in the recent valuable remedy for the swine plague. Hoping you may see fit to give us active support,

Yours very truly, G. E. TYLER, M.D., Sec'y.

A Rare Accident in Childbirth.

BUTTE, MONT., Feb. 19, 1898.

To the Editor: The patient, Mrs. G. H. M., aged 26 years, weight about 125 pounds, of medium height, native of Scotland, was married to her second husband seven months previously. She had twice miscarried, her last pregnancy being three years ago. She was taken in labor at full term on July

8, 1897, in the evening. She was having strong pains. Digital examination revealed only sufficient dilatation to admit point of forefinger. The waters had escaped. The presenting part could not be certainly diagnosed by vaginal touch and she was too tender and nervous for an abdominal palpation sufficiently thorough for a satisfactory diagnosis of presentation and position. The os was very rigid. After watching her for some time I noticed no progress whatever in dilatation and that she was bearing her pains very poorly. In the discharges there was not the faintest trace of blood.

The best treatment which I have ever found for rigid os complicated with threatened nervous exhaustion is some form of opium in large doses. Three tablets, each containing morphia sulphate, gr. $\frac{1}{4}$; atropin sulphate, gr. $\frac{1}{150}$, were given hypodermatically. At 4:30 A.M. the pains were regular and strong and the patient had had a good rest. I found signs of a slight hemorrhage in the bed. Examination revealed a breech presenting in the sacro-left-anterior position. The presenting part had passed entirely out of the uterus and was resting under the pubic arch. The labor made slow but steady progress to a complete and safe delivery of a large male child which soon breathed and cried lustily. There was no perineal laceration. The placenta was delivered in fifteen minutes with vigorous contractions of the uterus. After delivery of the placenta I noticed something protruding from the vulva, which, with very gentle traction, separated from a slight internal attachment when it was discovered to be the os tiucæ complete and entire torn off from the cervix. Not a half pint of blood was lost during the whole confinement, notwithstanding this accident. No anesthetic was given. No particular pain was complained of.

Had this complication occurred under powerful uterine action, goaded on by ergotic stimulation, it would have been less wonderful, although such an event I believe to be unheard of. But in this instance the tear took place while the patient was under the sedative and eminently relaxing influence of the morphia and atropin as above. Moreover, it happened without her being, apparently, in the slightest degree conscious of it. Her recovery was quite protracted. No hemorrhage. No odor to lochia. She had no milk for the babe, who has thrived vigorously on the bottle. She developed a phlegmasia dolens of moderate severity on one side and was very weak and feeble for three or four weeks. Her temperature would range from 100 to 103 degrees. Tablets of protonuclein and elixir digitalin seemed the most efficient medication. Milk and stimulants were used freely. She has menstruated regularly since, but more profusely than naturally. The uterus was examined a few weeks ago and found to be granulating nicely around the site of the tear.

J. S. HAMMOND, M.D.

The Humane Society Deal in Fiction.

The following is a copy of a letter addressed by the Humane Society to a well-known Senator:

WASHINGTON, D. C., Feb. 19, 1898.

Dear Sir:—I desire to call your attention to the bill now before Congress, "for the further prevention of cruelty to animals in the District of Columbia," and intended for the humane regulation of the practice of vivisection.

It is not, as has been by some erroneously supposed, an "antivivisection bill," but provides only that experiments upon animals shall be performed only by properly qualified persons; that in experiments calculated to give pain, the animal shall be rendered insensible by anesthetics; and it also provides for the appointment of four inspectors, appointed by the President of the United States, to see that these regulations are complied with and to serve without pay.

Ordinary inoculation experiments are expressly excluded from the operation of this law.

We wish to point out to you that, to the certain knowledge

of the Humane Society, there are perpetrated in this country, under the name of scientific research, acts of the most revolting cruelty and barbarity; that the young of both sexes are being trained to these practices; that even in the professions of medicine and surgery, whose devotees should be of all men most humane, they are now being educated by these means to an utter indifference to the infliction of pain and the sacredness of human life; that, to our certain knowledge, this rage for experiment, engendered by its unconstrained exercise upon animals, reacts upon human subjects placed, when ill, at the mercy of persons so trained, and especially upon the sick poor in hospitals, of whose abuse by such experiments there are many known instances.

We know that cruel vivisections have been done in the District of Columbia, though to what extent we can not know, owing to the secrecy with which such experiments are surrounded. We wish, however, to provide against them for the future.

Our opponents in the District claim that they now do nothing to which the bill objects. If their conduct is already in conformity with its provisions, their opposition is absolutely without cause, and they should be glad to forward legislation to prevent the hideous abuses known to exist elsewhere from creeping into our institutions.

Indignation has been expressed that anyone should attempt to put medical and scientific men under the control of law, but we submit that there is no reason why persons of this class should be more exempt from law than merchants or bankers or other classes for whose control special laws are framed.

We call your attention to the enclosed cutting, a synopsis of the report made by Senator Gallinger of the Senate "Committee of the District of Columbia," which reported the bill favorably without one dissenting voice; also to the fact that a petition in favor of this bill has been submitted to Congress of which Senator Gallinger, in presenting it, said that "probably no bill was ever presented to Congress which received the endorsement of so distinguished a list of men and women."

We beg that you will carefully consider and vote for this bill.

[Signed]

A. S. PRATT.

For the Humane Society.

The Illinois State Board of Health.

SPRINGFIELD, ILL., Feb. 28, 1898.

The 19th and 20th Annual Reports of this board, to be published very shortly, will contain an official register of all licensed physicians practicing in Illinois. As the reports are sent to every State in the Union, and are largely called for by professional and business men interested, I desire that the register be as correct as possible; hence would ask that you kindly accord me space in your journal to ask that every physician who wishes to have his name and address correctly reported will send the information to us on postal card at once, giving number and date of certificate.

In over 70 per cent. of cases the addresses on file in this office are those originally given when the certificates were issued, and as no additional information has been furnished this office, either by the county clerks or the physicians concerned, many physicians are reported from towns from which they moved several years ago.

J. A. EGAN, M.D., Sec'y.

Bismuth Capsules—A New Application for the X-Ray.

BUFFALO, N. Y., Feb. 21, 1898.

To the Editor:—In your issue of February 19, you quote from a report of Boas and Dorn, in the *Deutsche Med. Woch.*, regarding the use of capsules of bismuth for location of lesions in the alimentary tract. As this is an important matter, in

regard to which priority is, naturally, a matter of interest, will you kindly put on record the following data.

Feb. 9, 1897, I used gelatin capsules containing reduced iron for this general purpose, having had the matter in mind for some months. This experiment was a failure, on account of lack of power of X-ray apparatus, so far as the stomach was concerned, though the capsules could be plainly seen in the mouth. July 13, 1897, this method succeeded with three or four patients, using both iron and bismuth in the capsules. These experiments are more fully reported in *Medicine*, February, 1898. Very truly, A. L. BENEDICT, M.D.

Collective Investigation on the Action of Cold in Pneumonia.

PHILADELPHIA, PA., Feb. 26, 1898.

To the Editor:—My three collective reports already published on local cold applications in the treatment of acute pneumonia give a record of 299 cases so treated, with ten deaths, or a mortality rate of 3.35 per cent.

Being desirous of pursuing this investigation still further, I take the liberty of asking those who have tested this measure to kindly give me the result of their experience. Full credit will be given to each correspondent in the report which I hope to publish soon. Blanks for the report of cases will be cheerfully furnished by me, with postage for return of same, on application. THOMAS J. MAYS, M.D.

1829 Spruce Street.

Concerning Squirrels.

SANTA CLARA, CAL., Feb. 19, 1898.

To the Editor:—I wish to add a few observations and facts, regarding squirrels, gathered about the inhabitants of the trees of southwestern Michigan.

During the breeding season squirrels like other quadrupeds are very apt to fight. During this time the males battle violently. Their mode of battle is to chase each other until a favorable opportunity presents itself for one or the other to dart beneath the flank of his adversary and bite off his testicles. Sometimes both males share the same fate at the same time. The chisel-shaped teeth together with the ability to take a large round object into the mouth of the squirrel, makes it an easy matter for this animal to maim his adversary in this way almost instantly.

Instead of gray or fox squirrels castrating their own male young the credit must more often be given the agile little red squirrel who is the hardest fighter of them all. He is much quicker than his larger brothers of the other varieties and being smaller and shorter than they, can dart under them, perform his operation and escape before they can harm him. However, the red squirrels deprive each other of the testes during the breeding season. The chipmunk does the same thing. There is no mistaking a female squirrel for a castrated male, as the penis of the male is located under the belly instead of in the perineum, as in the cat. More than that, like the dog and the raccoon, the squirrel has a small bone in his penis which I have verified by dissection in an old male squirrel. The testicles of any old male of the squirrel are larger than those of the cat and hang in a pendulous manner. It is not strange that they should be bitten off readily by members of their own kind, when we consider the teeth and habits of feeding, etc.

I will conclude by showing that castration of his adversary is the squirrel's customary mode of warfare. I once captured an old male red squirrel alive and unhurt. I put him in a box with a large male ferret, expecting of course that the ferret would make short work of the squirrel. Instead of that the ferret had a very narrow escape from losing his testicles. It was only by backing into a corner and crouching down hard that he managed to protect himself until I came to his rescue

with a stick. The squirrel makes no other attempt to bite or harm his adversary in combat than to castrate him. He is an expert at it too, as the very large number of eunuchs among male squirrels will testify. I have seen them fighting many times. Yours truly, E. H. SMITH, M.D.

How Squirrels Become Eunuchs.

CRAIG COLONY, SONYEA, N. Y., Feb. 22, 1898.

To the Editor:—Relative to the discussion now going on in the *JOURNAL* on the above subject, let me say that many years ago it was my pleasure to spend several weeks each fall for five successive years in squirrel-hunting in the eastern section of middle Alabama. My daily tramps in the sport were made with an elderly companion, a man of 60 years, who all his life had been an ardent lover of the sport, and who loved nothing better than the daily rambles through the great forests where the tallest trees grew and where gray and red squirrels (the latter also known as the fox squirrel) abounded.

One day I shot a young male and on picking him up was surprised to find the entire scrotal sac missing, with evidence of a recent injury to the parts. I called my companion's attention to it. "Castrated," he promptly replied. "How?" I asked. "By an old male squirrel," he said, and added that he had often found the same thing, and that he felt convinced that it was done by the old males before the young males left the nest, and that he had on more than one occasion found two young castrated squirrels in one nest. On asking what he thought the old male's motive was for doing it, he answered like the horn philosopher he was: "I don't know; you had better ask the old male squirrel." Very respectfully,

WM. P. SPATLING, M.D.

Eunuchism of Squirrels.

ELLCOTT CITY, MD., Feb. 25, 1898.

To the Editor:—The theory has been advanced by many hunters I have met that during the absence of the mother squirrel, the young utilize the male appendages as teats and in their kind effort to produce something that is not there, cause in time an atrophy of the organs. Personally, though I have killed many squirrels, I have never seen a male minus his testicles, due, probably to the fact that I have never searched specimens for their presence or absence, save as I skinned them for use on the table. I very much doubt the theory of the older males castrating the younger ones; there is no reason why this should be done, and betrays more sense than the animal's gray matter or habits would warrant. A study of the incisor teeth of the squirrel would also suggest a difficulty in performing the operation in the clean manner suggested by your correspondents, or in a manner that would render the operation anything but fatal.

Could it not be a congenital absence of the organs, or failure of the organs to descend into the scrotum, in many of the reported cases when they are absent?

SAMUEL J. FORT, M.D.

A Coroner's Perquisite.

ELIZABETH, ILL., Feb. 1, 1898.

To the Editor:—One of your "Selections" in which the *London Lancet* is quoted has no doubt found many readers who will profit thereby. And as the medical profession can do much to dispel erroneous ideas, the writer would continue to call attention to errors in the manner of calling a coroner's attention when his services are needed. In my jurisdiction good judgment is not lacking in freeing a body found suspended, etc. Quoting from the article in the *JOURNAL* of January 29, p. 263, "If life remains a medical man should be sent for and afterward the police." The sending for a medical man while life still exists may at times be forgotten, hence the necessity

of calling attention to this matter. If a body is found *dead* the finder almost invariably sends for the police, and this officer may or may not send for the coroner. I do not think any good reason can be given for this circumlocution. The police usually search the unfortunate's pockets for letters, money, etc. In this way, before the arrival of the coroner, the lay press often gets sensational information that should not be published, and in this manner a genuine clue is often lost sight of and a police theory hovers in its place. Dr. E. W. Hoeber when coroner of New York City, found it necessary to complain to the chief of police. When the error was pointed out to him he instructed his captains as to the law, and that they must act accordingly and not search the body. It required a second visit on the part of Dr. Hoeber (several months afterward), when it again became apparent that the "chief's" instructions had been forgotten. This searching is clearly the duty of the coroner, for the reason that a coroner in Illinois is obliged to give a bond of \$5000 in each county except Cook, where a bond of \$15,000 is required, so that letters or moneys found will be safely kept for those to whom they rightfully belong. It should be a sacred trust with coroners to guard private affairs disclosed in letters, etc., from the public when they have no bearing in serving the ends of justice.

When a body is found *dead* there is only one proper way. *Send direct* to the coroner. Any man or woman should assume this authority. Medical men often have an opportunity and should instruct the people (including the police) that they have no right to take charge of or search a body *found dead* unless the coroner gives this authority. A prominent attorney who had become mentally deranged, took his own life in his office. A doctor and an attorney first discovered the dead body and in due time the deputy sheriff telephoned me. Later a night policeman, hearing of the attorney's death by suicide, went to the place and was in the act of making a forced entrance, as the rooms had been locked after the body was discovered. The layman above mentioned insisted that the night police should desist, as the coroner had been notified. No forced entrance was made. It was generally believed that this attorney took his own life because of absolute want. At the inquest this was disproved from the fact that a considerable amount of money was taken from his pockets. The doctor and attorney who found the dead body would have been justified in sending for the coroner *direct*, instead of serving notice through the deputy sheriff. Much more might be written on the abuse of the coroner's office, and when this matter is properly understood and acted on little more will be heard of the "obsolete coroner system."

PHILIP ARNOLD, M.D.

PUBLIC HEALTH.

Individuality a Factor in Birth Rates.—Dr. D. G. Brinton, once editor of the *Philadelphia Medical and Surgical Reporter*, in a recent article in *Science*, after quoting from the *Journal de la Société de Statistique de Paris*, November, 1897, an article by Arsene Dumont regarding the diminished birth rate of New England, gives his own conclusions. He finds the chief cause in the principle of democracy, which contains a toxic principle. The more intense republican civilization, the more acute becomes individualism, or the overpowering desire to live to the best personal advantage and to get all the good there is going, be it in the sphere of intellect or other gratification. But the numeric increase of the race is and must be inversely to the effort of the individual to develop himself personally. There may, however, be a democracy directed by science which can escape this poison. With this cheering but vague intimation the article closes.

The Results of Immunizing Experiments in Hog Cholera. Voges and Schutz announce that immunity is only secured when the

bacteria circulate in the blood, and that killed rothlauf cultures produce immunity as soon as they are inoculated directly into the blood. The immunizing substances comprised in the cultures are contained within the bodies of the bacterial cells. These cells are protected, however, by a wax-like resistant envelope which it is impossible to destroy by the Koch mechanical process, or by any of the known chemic agents, except lyse, which destroys the immunizing substance as well. But the action of one or more of the organs of the organism is able to destroy this protecting shell and liberate the anti-bodies within it and thus induce immunity. The germs in the body are thus naturalized by: 1. The opening up of the bacterial shell by the activity of some organ. 2. The destruction of the bacterial protoplasm by the bactericidal protecting substances then liberated and dissolved in the blood serum.—*Deu. Med. Woch.*, February 3.

Antiseptics in the Preservation of Meats.—M. Duprez has recently presented a report to the Board of Health of the Seine, Paris, in which he calls attention to the increasing use of antiseptics by butchers for preserving meat. The product most generally used is olobar, which is nothing but a solution of bisulphate of calcium, containing 99 grams of sulphurous acid to the liter. Riche claims that the use of this compound is daily increasing and it is now extensively used in beer. It is claimed by the manufacturer of olobar that its use is harmless in that it does not cause the meat to undergo any appreciable change. This, however, hardly seems probable when we consider that we submit our staple food stuffs to the influence of agents as active as sulphurous acid and the sulphites; neither does it seem tenable that their action would be limited to the initial products of fermentation so as to absorb them and counteract their efforts. Experiments have demonstrated that a 1 to 8 solution of calcium bisulphite will penetrate very deeply the meat soaked in it and that the normal structure and muscular fiber does not remain the same, hence the refrigerating process alone should be relied upon for the preservation of meats.

Municipalities not liable for Negligence of Boards of Health.—In the case of *Gilboy vs. the city of Detroit*, it was alleged that the plaintiff kept a boarding-house; that he received a boarder in the usual course of business; that said boarder had been exposed to smallpox at the Merchant's Hotel in the city of Detroit, and that, through the negligence of the Board of Health, said person was permitted to go at large, instead of being confined; that it was the duty of the Board of Health, under the charter and ordinances of the city, to examine the person at the Merchant's Hotel, determine whether she had smallpox, and, if she had, to remove her to a pest-house or hospital; that the person received into the plaintiff's boarding-house was taken down with smallpox while there, and he, in consequence, suffered loss and damage. The facts were not denied, and thus was presented for adjudication, the sole question of whether a municipality is liable for the negligence of officers of the Board of Health in the performance of their duty? The supreme court of Michigan decides it in the negative, December, 1897. It says that counsel for the plaintiff cited no authorities to support their contrary contention, probably for the very good reason that none could be found. The universal rule is, declares the supreme court, that such boards and officers are not acting for private, but for public purposes; they represent the entire State, through the municipality, a political subdivision of the State; and municipalities, in the absence of express statutes fixing liability, are not liable for the negligence of such officers and boards.

Increasing Ophthalmia and Blindness in New Jersey. The New Jersey State Board of Health has made public the following statement on the above subject: "The increase of blindness in New Jersey is five times more rapid than the increase in

population, and purulent ophthalmia, an infectious and therefore a preventable disease, is believed to cause not less than 30 per cent. of all cases of blindness." This statement is admitted to be based not on any official statistics, since such are not available, but the information comes direct from the members of the medical profession who have been watching the increase of the disease. The State Medical Society of New Jersey, at its meetings in 1893 and 1894, discussed the subject at great length and drafted the bill that is now on the statute books, which is intended to limit the prevalence of the disease. The neglected law makes it compulsory on any attendant, nurse, midwife or relative of an infant that has inflamed, swollen or reddened eyes to report the fact immediately to the local health officer, who shall at once see that the attendance of a physician is secured and the baby taken care of. It is incumbent on health officers to notify all midwives and others who attend upon births, of the terms of the law, and that a penalty by imprisonment or fine or both may be incurred for neglect to report all cases of inflamed eyes.

BOOK NOTICES.

A Text Book on Surgery, General, Operative and Mechanical. By John A. Wyeth, M.D., Professor of Surgery in, and President of the Faculty of New York Polyclinic Medical School and Hospital, etc., etc. Third edition, revised and enlarged. pp. 997. New York: D. Appleton & Co., 1898.

The original edition of this work was published in 1886; a second edition in 1890. The following from the author's preface to the third edition gives the scope of the work: "The introductory section is devoted to surgical pathology, subdivided into six chapters, which treat of inflammation, process of repair in various tissues of the body: specific and non-specific urethritis: erysipelas and actinomycosis; glanders, tetanus, malignant edema, hydrophobia, tuberculosis, syphilis, leprosy, diphtheria, typhoid infection, are also embraced in this portion of the work. Chapters 7 and 8 are devoted to surgical dressings, sterilization, asepsis and antisepsis, and anesthesia. In chapters 9 and 10 much attention is given to hemorrhage, wounds, burns, skin-grafting, frost bite, furuncle, carbuncle, ulcers and gangrene. Bandaging is given in chapter 11. Chapter 12 is devoted to amputations. Chapters 13, 14 and 15 deal with lymphatic vessels, glands, veins, arteries, aneurysm and ligation of vessels. Chapters 16 and 17 give the lesions of the bones and joints and various operative measures for their correction. Chapters 18 to 29 inclusive are devoted to regional surgery, and in that portion of this section in which the abdomen is concerned, many improved changes have been made and much new matter added. Chapter 30 takes up deformities and their correction, while the final chapter, 31 is devoted to the subject of tumors."

Wyeth's Surgery has always been a favorite with students and practitioners. While preserving the features that made the former edition popular, the matter has been brought down to date.

Treatise on the Diseases of Women, for the use of Students and Practitioners. By Alexander J. C. Skene, M.D., LL.D., Professor of Gynecology in Long Island College Hospital, Brooklyn, N. Y., etc., etc. Third edition, revised and enlarged; 290 engravings, and 4 plates in colors; pp. 991. New York: D. Appleton & Co., 1898.

The former editions of this work were issued in 1888 and in 1892. The great strides that have been made in gynecology since the last edition of this work was issued have made it necessary to issue a new one, and the author has conscientiously made a revision which brings it down to date; consequently we find a fuller discussion of vaginal and abdominal hysterectomy than in any former editions, and the latest improved methods of performing these operations given. The control of hemorrhage by compression and electric heat receives much attention, and in a manner which will interest the general as well as the special surgeon. The electric hemostatic forceps devised by

Skene as shown in pages 427 and 431, is clearly a great advance over the ligature in the performance of vaginal hysterectomy. The degree of heat is not one which will produce an eschar but 170 to 190 F., the length of time which the electric hemostatic forceps are applied should be heated, varies from 30 seconds to 2½ minutes, depending upon the thickness of the tissue compressed between the jaws of the forceps. An excess of current for a few seconds before the commencement of its application seems to be necessary. These forceps require less electric energy than the average cautery electrode, but the current from the electric light main can be used, and is preferable as the care and attention necessary to keep a battery in working order are avoided. A "transformer" is necessary.

Twentieth Century Practice; An International Encyclopedia of Modern Medical Science, by Leading Authorities of Europe and America; edited by THOMAS L. STEDMAN, M.D., New York City; in 20 volumes; Vol. 13, "Infectious Diseases," pp. 621. New York: Wm. Wood & Co., 1898.

The chapters of this volume are by P. Brouardel, M.D., of Paris; Jules Comby, M.D., Paris; Harold C. Ernst, M.D., Boston; Ernest Hart, D.C.L., London; John Wm. Moore, M.D., Dublin; Solomon C. Smith, M.D., London; Victor C. Vaughan, M.D., Ann Arbor, and Lawson Williams, M.D., London.

The articles are as follows: Ptomaines, toxins and leucemias; infection and immunity; water-borne diseases; the duration of the period of incubation and infectiousness in the acute specific diseases, smallpox, vaccinia, mumps. In Dr. Comby's article on mumps, he quotes Catrin's observations of Val de Grâce in 1892. He says: "Of ninety-five cases of mumps, which formed the basis of our studies, we obtained positive results in sixty-seven. Thirty-nine out of fifty-six times we obtained pure cultures by puncture of the parotid glands; twice the cultures were impure, and fifteen times no result was obtained. These negatives may be explained by the occasional absence of any fluid in the organ, so that the plate were sown merely with sterilized water contained in the needle. In most cases the amount of fluid extracted did not exceed a few drops. The testicular fluid, on the other hand, almost constantly gave positive results, that is, in twelve out of sixteen experiments the fluid removed from points of localized edema gave a positive result in all cases examined (three), and the same was true in the two cases in which fluid from the swollen knee-joint was examined. In ten out of fifteen examinations of the blood while fever was present, the same microorganisms were found as in the fluid removed from the various organs. We found microbes two, and even three, weeks after apparent recovery from mumps, a fact which serves to explain the rare instances of contagion during convalescence. After a month elapsed our researches were always negative in their results. . . . The organisms found by us were micrococci usually arranged in pairs, sometimes in fours, and rarely in zooglea masses. These cocci measured from one to one-and-half micromillimeters in diameter; they were mobile, but not markedly so. They were colored readily with the ordinary stains, but unlike streptococci and staphylococci, they did not receive Gram's staining. The bouillon, kept in an oven at 3 degrees C., showed changes at the end of from 20 to 24 hours and these increased markedly later. Colonies on gelatin plates did not appear until the expiration of 48 hours; they were punctiform, white in color, grew slowly, and liquified also very slowly and tardily. In stab cultures the colonies developed as very minute pearls along the track of the puncture; liquefaction began at the surface and proceeded very slowly. On potato the whitish culture was scarcely apparent, but it was more so on carrot."

Inoculation experiments were unsatisfactory, since no known animal, except perhaps the horse, is susceptible to mumps. In white mice four out of twenty inoculations were followed by

path, and on examination the spleen was enlarged. Four of these inoculations were made in the peritoneum, and in three of them death occurred. In all fatal cases the diplococcus was found in the blood removed from the heart cavity with all the usual precautions. Busquet and Ferré found a similar diplococcus in seventeen cases in the blood taken from the pulp of the finger and lobe of the ear and in the fluid from the parotid gland. Mecran and Walsh also isolated and cultivated this diplococcus in cultures made from the contents of Steno's duct during the height of the disease. Michaelis also found this diplococcus. Notwithstanding these reports, Comby is of opinion that the final experimental proof is wanting, that is, the production of the disease in animals by inoculation.

The American Year-Book of Medicine and Surgery. Being a Yearly Digest of Scientific Progress and Authoritative Opinion in all Branches of Medicine and Surgery drawn from Journals, Monographs and Text-books by the Leading Foreign Authors and Investigators: Collected and Arranged with Critical Editorial Comments by Twenty-seven Authors, under the General Editorial Charge of GEORGE M. GOULD, M.D. Illustrated, pp. 1077. Philadelphia: W. B. Saunders. 1898. Price, cloth, \$6.50; half-morocco, \$7.50. For sale by subscription. Dr. Gould says: "The largely increased demand for the 1897 Year-book leaves no doubt as to the usefulness of our work and of appreciation on the part of the profession. These facts have increased the endeavor of all concerned in the preparation of the volume for 1898 to bring it more nearly to our ideal of perfection. With the growing clearness of conception on the part of the editors of the exact nature of the professional need, there has been a corresponding recognition of the necessity of keeping the epitomization within the limits allotted for previous issues. The vast and increasing literature has thus far rendered the task of the editors of especial difficulty; but we believe it has been more thoroughly carried out than ever before, despite the protests of most of the editors that any possible sine of omission must be charged to 'insufficient space,' and not to neglect."

This volume has a copious index. No library is complete without Gould's Year-book.

Notes on Aseptic Technique. By A. D. WHITING, M.D., Assistant Surgeon to the German Hospital, Philadelphia. Pp. 157. Philadelphia: J. B. Lippincott Co. 1898. Price \$1.00.

The object of this book is to aid those whose duty it is to prepare materials for an operation. It is divided into six admirably written chapters, and will be found very useful for the purposes for which it is intended.

Transactions of the Royal Academy of Medicine of Ireland. Volume X. Edited by JOHN B. STORY, M.D., F.R.C.S., General Secretary; Surgeon to St. Mark's Ophthalmic Hospital, Dublin. Pp. 477. Dublin: Fannin & Co. 1897.

The contents of this volume includes a list of officers, fellows, members, etc., as well as an address by Prof. Wilhelm His upon the Development of the Brain, and the papers and discussions of the section of medicine, section of surgery, section of obstetrics, section of pathology, section of state medicine, section of anatomy and physiology. The number and variety of illustrations in the volume are remarkable, and the papers are of a high order of merit.

Transactions of the American Microscopical Society. Vol. xix. Paper. Pp. 207. Buffalo: 1897.

This volume contains the proceedings of the twentieth annual meeting, held at Toledo, Ohio, Aug. 5, 6 and 7, 1897. The following papers, with numerous colored plates, are noted, among others: "Micro-structural characteristics of steel," "The life of Sandusky Bay," "The comparative histology of the digestive tract," "A comparison of the phagocytic action of leucocytes in amphibia and mammalia," "A comparative study of hair for the medico-legal expert," "A study of the sense of taste," "Development of methods in microscopic technique," "Notes on the isolation of tissue elements,"

"Dahlia as a stain for bacteria in sections cut by the collodion method," "Two very simple microtomes."

Eleventh Annual Report of the State Board of Health of Ohio for the year ending Oct. 31, 1896. Cloth. Pp. 376. 1897.

This volume contains the general report of the State Board, annual reports of local boards for the year ending Dec. 31, 1896, additions to the library of the State Board, a list of cities and villages having boards of health with name of health officer, a report of infectious diseases for the year ending Jan. 2, 1897, reports of deaths and their causes for year ending Dec. 31, 1896, and an eighty-page appendix covering the proceedings of the seventh annual meeting of the State Board and local boards, held in Columbus, Jan. 21 and 22, 1897.

Transactions of the Medical Society of Virginia. Paper. Pp. 290. Richmond: 1897.

This volume covers the proceedings of the twenty-eighth annual meeting of the Society, held at Hot Springs, Va., Aug. 31 and Sept. 1 and 2, 1897, and contains twenty-two papers presented to the Society, general discussions, obituaries, list of presidents and vice-presidents, with statistic data of value to the physician. An appendix contains a biographic register of Fellows of the Society.

Transactions of the Medical Association of Georgia. Cloth. Pp. 535. Atlanta: 1897.

The volume is on excellent paper and of good typography and workmanship. The contents comprise the proceedings of the forty-eighth annual session, held at Macon, Ga., April, 1897. Among the forty-four papers printed we notice: "Enterocolitis of infancy," "Blue pyoktanin in the treatment of inoperable malignant growths," "Morphin and its effects," "Atropin poisoning," "Eucain, with report of a case," "Dermoid cyst of bladder," "Meddlesome instrumentation in urethral disease."

Sir James Young Simpson. By H. LAING GORDON. New York: Longmans, Green & Co. 1897.

This is the third volume of the series of "Masters of Medicine," and the subject is in every way a worthy one. Sir James Simpson's works have always been read with admiration in America, and the older members of the profession owe much to those unrivaled "Lectures on the Diseases of Women," published by Blanchard and Lea in 1863, which had such a wide circulation here. The enumerated list of titles of his works in the Surgeon-General's "Index Catalogue" is prodigious in number and scope. Dr. Gordon has given us a faithful biography of this remarkable man, and it is one of the most interesting volumes of the series so far printed.

NECROLOGY.

EDWARD CONSTANT SEGUIN, M.D., who died at his home in New York City, February 19, was the only child of the late Edward O. Seguin, M.D., whose brother, father and several relatives of the same name were physicians, chemists, engineers and architects. Born in Paris, France, in 1843, he was brought to America with his father, who in 1850 took up his residence in Cleveland, Ohio, at which city and in Portsmouth, of the same State, he received both a public and high school education. In 1861, then living at Mount Vernon, N. Y., he began the study of medicine with his father, and after a three years course at the College of Physicians and Surgeons, New York, was graduated in 1864. During this time he acted as dresser in the hospital steamship of the United States Sanitary Commission in the Pamunkey and James Rivers and served as a medical cadet of the regular army until 1864. From September, 1864, to June, 1865, he was an acting assistant surgeon, U. S. A., and during the last two months an assistant surgeon, U. S. V. Afterward he became a member of the house staff of the New York Hospital for the usual term of

two years. In consequence of the development of pulmonary trouble, he was by courtesy of the then Surgeon General assigned to New Mexico and there served as post surgeon at Forts Craig and Selden. In the summer of 1869 he returned to New York with his health apparently completely restored. Soon after the opening of the Connecticut Hospital for the Insane, Dr. Seguin was appointed pathologist for the same and so continued for about ten years. The winter of 1869-70 was spent by him in Paris under Brown-Séquard, Charcot, Ranvier and Cornil, but upon his return to New York he took up general practice instead of his intended specialty. From 1871 to 1885 Dr. Seguin was a lecturer on diseases of the spinal cord, and in 1873 founded the Clinic for Nervous Diseases in the College of Physicians and Surgeons, New York. Between 1882 and 1893 he was in Europe several times, but resumed the practice of his specialty whenever he was in New York. His popularity was great and his fees ample. His literary work was limited to monographs of more or less excellence, but compensation was had in the acuteness of his diagnosis and the felicity of his diction. He was a member of many societies in both hemispheres and often spoke with satisfaction of his relations with the various neurologic societies. He leaves a second wife but no children. His death was due to cirrhosis of the liver.

WILLIAM T. ELMORE, M.D., Dartmouth, 1888, died from pneumonia in New York City, February 12, aged 44 years. His birth-place was Montgomery, Ala. He went to New York fifteen years ago.

CONANT SAWYER, M.D., Albany, N. Y., 1865, died at his home in Auburn, N. Y., February 21, after a week's illness from pneumonia. He was physician of Auburn Prison for ten years, having come from Ausable Forks. Besides being a member of several organizations he was identified with the AMERICAN MEDICAL ASSOCIATION and a founder of the New York State Medical Association.

GAMALIEL GILLIS, M.D., N. Y. University Medical College, 1885, of Montagus Bridge, Prince Edward Island, Canada, died January 4, aged 45 years.

ENNIS I. GERAGHTY, M.D., formerly a house physician of St. Vincent's Hospital, died at his home in New York, February 18, aged 23 years.

LEWIS FRENCH, M.D., N. Y. University Medical College, 1883, died January 27, at his home in Noroton, Conn., where he was a member of the hospital staff of the Soldiers' Home.

DANIEL CAMPBELL, M.D., died at Saxton's River, Vt., Feb. 3, aged 77 years. He was graduated from the Vermont Medical College at Woodstock in 1842, and from the Berkshire Medical College, Pittsfield, Mass., in 1843. He practiced in Pittsfield, was in Westminster ten years, and since 1854 had lived at Saxton's River. He was a member of the Legislature in 1864, and was a nominee for Congress in the Second District, in 1880.

JOHN S. ISHAM, M.D., Bellevue, N. Y., 1874, died in Cleveland, O., February 10, aged 50 years.—Montague L. Boyd, M.D., Savannah, Ga., of blood poisoning contracted in performing an operation, February 9, aged 48 years.—D. B. Collins, M.D., St. Peter, Minn., February 14.—T. P. Crutcher, M.D., Nashville, Tenn., February 13, aged 68 years.—Frederick B. Gould, M.D., Kent, N. Y., February 13, aged 38 years.—John P. Hillegas, M.D., Philadelphia, February 12.—T. P. McCullough, M.D., Fort Wayne, Ind., February 18, aged 75 years.—Oscar A. Menocal, M.D., Washington, D.C., February 9, aged 28 years.—Hiram L. Spicer, M.D., Baltimore, Md., February 12.—Jonathan S. Whitaker, M.D., Millville, N. J., February 14, aged 75 years.—Lewis R. Hurlbutt, M.D., Yale, 1850, of Stamford, Conn., February 14, aged 78 years.—James Wilkinson, M.D., College of Physicians and Surgeons, N. Y., 1858, died in Jersey City, N. J., February 17, aged 61 years.—Heinrich N. Hahn, M.D., St. Paul, Minn., February 22. He was graduated from the University of Marburg, Germany, in 1874.—Sylvester C. Ham, M.D., Auburn, Ill., February 22, aged 46 years.

JOHN G. TRUAX (*vide* JOURNAL, p. 507).

WHEREAS, We the members of the Medical Board of the Harlem Hospital, have learned with deep regret of the death of our late associate, Dr. John G. Truax,

Resolved, That we record our recognition of the value of his services in the establishment, due largely to his untiring energy, of the Harlem Hospital, the organization of which was his work.

Resolved, That we hereby desire to express our appreciation of his manliness and decision of character, his high sense of professional honor, and the zeal and ability shown by him in the practice of the profession which he loved.

Resolved, That a copy of these resolutions be sent for publication to the *New York Medical Record*, *New York Medical Journal*, to the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, and to the widow of Dr. Truax.

[Signed] J. T. JOSEPH BIRD, M.D., Sec.

DEATHS IN THE PROFESSION ABROAD. — Dr. P. di Pietra Santa, aged 77. A notable and picturesque figure in Paris, founder of the Société d'Hygiène and editor of its journal, prominent in every phase of the progress of hygiene, author of numerous studies on climatology, influence of warm climate on tuberculosis, etc., and one of the earliest partisans of cremation. "Born in Corsica, he was related to Bonaparte, and when he first settled in Paris was physician and secretary to the old king, Jeroms of Westphalia, and later to his son, Prince Napoleon." He had many friends in America and the *Journal d'Hygiène*, under his able editorship, was greatly respected and admired.

SOCIETY NEWS.

Chicago Medical Society.—A clinical meeting was held Feb. 2, 1898, with the President, Dr. Fernand Henrotin, in the Chair. Dr. Daniel R. Brower exhibited four cases of exophthalmic goiter in a family of six children. The four children had tachycardia, pulsating goiters, and one of them marked exophthalmus. Dr. G. W. Johnson exhibited a case of tabes dorsalis with Charcot's ankle joint. The man was 45 years of age, single, and a sail-maker by occupation. He gave a history of having had a chancre sixteen years ago, also of a second syphilitic infection seven years ago. He also exhibited a case of syringomyelia. The patient was a Swede, 39 years of age, unmarried, and a molder by occupation. Dr. L. D. Baldwin showed a Chinaman with an ulcerative syphilitic process on the face. Dr. N. Senn presented two cases in which transcapular amputation was performed for periosteal sarcoma. Dr. E. E. Ochsner showed a case of compound comminuted fracture of patella because of the good result obtained by the use of chromicized catgut sutures. Dr. Moreau R. Brown exhibited an apparatus for washing instruments and heating sprays. Dr. Elbert Wing showed specimens from a case of intussusception. Dr. A. J. Ochsner showed a specimen illustrating the condition of appendicitis obliterans. He also exhibited multiple fibroids of the uterus. Dr. F. E. Chandler exhibited a monstrosity.

Illinois State Medical Society.—The forty-eighth annual meeting will be held in Galesburg, May 17, 18 and 19, 1898. The preliminary program announces addresses by Drs. J. H. Etheridge and N. Senn of Chicago, and J. W. Pettit of Ottawa. The following papers are also announced:

"Malnutrition in Infants," Frank P. Norbury of Jacksonville; "Infantile Scurvy," Isaac A. Abt of Chicago; "Tumor of Lung," Frank Billings of Chicago; "Diagnosis of Pleurisy with Effusion," Jas. B. Herrick of Chicago; "Etiology and Pathology of Pleurisy with Effusion," Ludvig Hektoen of Chicago; "Treatment of Pleurisy with Effusion," T. J. Pitney of Jacksonville and L. T. Taylor of Springfield; "Case of Patent Ductus Botalli," Frank S. Johnson of Chicago; "Chemical Examination of Inoperable Carcinoma," C. C. Hunt of Dixon; "Acute Tonsillitis," P. C. Thompson of Jacksonville; "The Presence of the Smegma Bacillus in the Urine and its Staining Qualities," J. L. Miller of Chicago; "Case of Brain

Disease," W. M. Friend of Sumner; "A Positive Antidote for Strychnia," L. R. Ryan of Galesburg; "Epileptics," J. B. Maxwell of Mt. Carmel; "Remarks on the Treatment of Neurasthenia," Hugh T. Patrick of Chicago; "Diabetic Gangrene," N. S. Davis, Jr., of Chicago; "Significance of the Diastolic Murmur in Diagnosis of Aortic Insufficiency," B. W. Sippy of Chicago; "A Pharmacologic Study of the Action of Digitalis on the Mammalian Heart and Circulation," S. A. Mathews of Chicago; "Modified Milk," J. S. Churchill of Chicago; "Summary of Laws Governing Medical Practice in other States," Julius Kohl of Belleville; "Defects of the Laws of this State Governing Medical Practice," G. N. Kreider of Springfield; "What Should be the Law in this State?" H. N. Moyer of Chicago; "Advantages of Separating the State Board of Health from the Licensing Board," L. R. Ryan of Galesburg; "Summary of Laws Governing Expert Testimony in other States and Countries," J. O. DeCourcy of St. Libory; "Defects of Laws Governing Expert Testimony in this State," Sanger Brown of Chicago and F. P. Norbury of Jacksonville; "The Outlines of a Law that would Remedy the Defect," D. W. Graham of Chicago; "The Legislation Necessary to Promote Better Sanitation Throughout the State," J. A. Egan of Springfield; "Labor in Fat Women," J. B. DeLee of Chicago; "Repair of Bones," H. C. Fairbrother of East St. Louis; "Surgical Treatment of Cavities in Pulm. Tub," H. M. Thomas of Chicago; "Straits of Early Life," J. O. DeCourcy of St. Libory; "A Contribution to the Surgery of Accidental Wounds of the Knee Joint," D. A. K. Steele of Chicago; "Cynovitis; Remarks on Treatment," C. W. Sibley of Fairfield; "Treatment of Minor Surgical Injuries with Especial Reference to Bandaging," J. J. Connor of Pana; "Laminectomy in Pott's Disease," A. H. Ferguson of Chicago; "Urinary Fistule," Wm. Cato of Decatur; "Early Operation for Uterine Cancer," F. H. Martin of Chicago; "Congenital Phymosis and Some of its Effects," Ed. C. Lemen of Alton; "A Substitute Operation for Resection in Certain Extensive Injuries to Intestinal Wall," E. C. Dudley of Chicago; "My Name is Appendicitis," Emma B. Standley of Alexis; "Path. Histology of Intestinal Anastomosis," J. Frank of Chicago; "Atrophic Rhinitis," E. T. Dickerman of Chicago; "A Case of Extra-Uterine Pregnancy," O. B. Will of Peoria; "Diagnosis of Pulmonary Cavities with Special Reference to their Surgical Treatment," R. H. Babcock of Chicago; "Surgical Shock," Robert A. Kerr of Peoria; "Interesting Cases of Mastoid Disease," Norval H. Pierce of Chicago; "Report of Cases of Casarean Section," A. McDiarmid of Chicago; "Toxemia of Pregnancy," J. T. McAnally of Carbondale; and papers by W. R. McLaughlin of Jacksonville and A. C. Corr of Carlinville.

American Laryngological, Rhinological and Otological Society.—The meeting of the Southern Section of the American Laryngological, Rhinological and Otological Society will be held in Atlanta, Ga., March 28, 1898.

Preliminary Program: Address by the Chairman, A. W. Calhoun of Atlanta; "Labyrinthine Vertigo," John Hey Williams of Asheville, N. C.; "Chromatic Audition," J. L. Minor of Memphis; "Report of a Case of Hemorrhage after the Removal of Adenoid Vegetations," Ross P. Cox of Rome, Ga.; "Hypertrophy of the Lingual Tonsil, its Symptoms and its Treatment," D. A. Kuyk of Richmond, Va.; "Thrombosis of the Lateral Sinus, Dependent upon Suppurative Otitis Media," E. B. Dench of New York; "Othematoma and Perichondritis of the Auricle," John O. McReynolds of Dallas, Texas; "Tracheotomy for Foreign Bodies in the Air-passages, Report of Twenty-seven Successful Cases," Willis F. Westmoreland of Atlanta; "Empyema of the Accessory Nasal Cavities," Ruffin A. Wright of Mobile; "The Influence on Development of the Nervous System of the Child by Adenoid Vegetations in the Nasopharynx," E. P. Sale of Memphis; "Nasal Fibromata, with Report of Cases," L. M. Crichton of Atlanta; "A Form of Primary Nasal Diphtheria," E. C. Ellett of Memphis; "The Importance of Examining the Nose in Troublesome Coughs," A. C. Palmer of Richmond, Va.; "Intubation of the Larynx for Membranous Stenosis," Bernard Wolff of Atlanta; "Mouth Breathing," Norburne B. Jenkins of Knoxville, Tenn.; "Mental Disturbance in Turbinate Hypertrophies or Nasal Stenosis," John F. Woodward of Norfolk, Va.; "A Discovery in the Physiology of the Ear," W. F. Cole of Waco, Texas; "Middle Ear Catarrh, Some Original Deductions," Maury B. Stapler of Macon, Ga.; "Ethmoiditis and Report of Case,"

B. F. Travis of Chattanooga; "Mastoid Inflammation, with a Report of Two Interesting Cases," T. E. Mitchell of Columbus, Ga.; "Mouth Breathing in Children, Particularly as a Result of Adenoids," Arthur G. Hobbs of Atlanta; "The Nasopharynx in Laryngeal Diseases," N. C. Steel of Chattanooga; "Cholesteatoma of the Mastoid Antrum," S. L. Ledbetter of Birmingham, Ala.; "Diseases of the Accessory Sinuses," Alex. W. Stirling of Atlanta; "Clinical Miscellanies from Private Practice," Frank M. Mullins of Fort Worth, Texas; "Empyema of the Accessory Sinuses of the Nose," Frank M. Hanger of Staunton, Va.; "A Good Hemostatic after Nasal Operations," L. B. Grandy of Atlanta; "Hypertrophic Rhinitis and its Treatment," F. J. Hill of Memphis; "The Serum Treatment of Ozena," W. E. Campbell of Atlanta; "Peritonsillar Abscess," Dunbar Roy of Atlanta.

All the hotels have given reduced rates and a large meeting is expected. The profession is cordially invited.

DUNBAR ROY, M.D., Secretary.

NEW INSTRUMENTS.

AN IMPROVED STETHOSCOPE.

BY F. W. MERCER, M.D.

CHICAGO.

In the stethoscope here illustrated an attempt has been made to combine the desirable features of a number now in use. The advantages claimed are increased clearness and distinctness of sounds transmitted; its lightness and the ease by which the whole instrument can be made aseptic. In its construction only thin and hard German silver tubing should be used, the chest piece being of the same material. The bell, or chest piece, differs to a degree from existing forms in having the bifurcation

carried down rather close to the rim and the bell itself made as short as possible. The mouth of the bell has a diameter of 25 mm. and each bifurcation has an internal diameter of 8 mm. The pure gum, antimony tubing connecting the chest piece with the ear tubes should have extra thick walls, with an internal diameter of 8 mm. The metal ear tubes made perfectly smooth within, not having screw points or rivets penetrating, to be 8 mm. internal diameter. The ear tubes are bent with the usual curve, somewhat shortened, and ear tips and all finished entirely in one continuous piece of metal, the margin of the openings turned down and inward, making a perfectly smooth surface to openings of 6 mm. diameter. The tips may, as shown in the drawing, be finished with a thin coating of celluloid. The spring is split longitudinally, giving increased elasticity. All the metal parts are finished in dead black or silver. Soft rubber hoods can be drawn over the mouth of the bell, increasing its size as desired.

MISCELLANY.

Dr. R. Harvey Reed, of Rock Springs, Wyo., has been appointed Surgeon General of the National Guard of that State, with rank of Colonel.

Skiagraphic Photometry.—With a light-proof, black paper box Biesalski determines at a glance the exact time required for radiographic exposure, by gauging the potency of the rays. The box is shaped like a cryptoscope and fits close to the eyes, with an opening at the other end for the Crookes tube. A fluorescent screen is divided into thirty-six spaces and on each

space a certain number of sheets of tin-foil are fastened, also a wire figure showing the number of sheets in each space: 1 for one; 2 for two, etc., up to thirty-six. The potency of the light is thus indicated at a glance by the figure on the last space through which it passes.—*Deut. Med. Woch.*, February 3.

Personal.—Dr. T. D. Crothers of Hartford, Conn., read a paper on "The Medical Side of the Alcoholic Problem" before the Alleghany County Medical Society at Pittsburg, Pa., Feb. 15, 1898.—Dr. John H. Noland of New Haven, Conn., has gone to Cuba to join the insurgents. It is understood that he is associated with two other medical men and they are supplied with a full hospital outfit to give modern aid to the modern patriots.

Vegetables a Fightlag Diet.—A writer in the *London Vegetarian* evidently with a bias, says that "99 per cent. of the world's fighting has been done on farinaceous food." "The Tipperary peasant of the potatoes and butter-milk days" he pits against "the modern gentleman who gorges himself with murdered cow. The Tipperary man never read bloody-minded novels or cheered patriotic music hall tableaux, but he fought recklessly and wantonly. Your carnivorous gentleman is afraid of everything, including doctors, dogs, disease, death and truth-telling."

Pay of Professional Men in France.—In France, according to *Paris Eclair*, there are from 12,000 to 13,000 doctors, of whom 2500 are found in Paris and about 10,000 in the provinces. Of this number five or six only make incomes of from \$40,000 to \$50,000 a year, ten to fifteen make from \$20,000 to \$30,000 a year, 100 make, say, \$10,000, 300 make from \$3000 to \$5000, 800 make from \$1500 to \$3000, while 1200 earn less than \$1500 a year. Coming to the lawyers, of whom there are 3000 in Paris alone, there are not 400 of them who make as much as \$2000 a year. A couple of score make incomes of \$10,000 a year. It appears that when one of these advocates is made a magistrate his salary is only from \$600 to \$800 a year, while for the justices of the peace, all fully qualified legal practitioners, the salaries range from \$400 to \$600 a year. A college professor is paid from \$200 to \$300 a year, a lycée professor from \$700 to \$1000 a year. The explanation is that in France there are too many doctors, lawyers, professors and engineers turned out.

Medical Works Not Affirmative Evidence except when used for the cross-examination of experts.—In a case decided by the appellate division of the supreme court in Brooklyn, N. Y., regarding the nature of the injury received by the plaintiff, who claimed that it was progressive in tendency, the counsel was allowed to read from Professor Gross's work the statement concerning the prognosis of nerve contusions. The justice tersely ruled that "the weight of authority on that subject is to the effect that books of inductive science, within which are standard medical works, are not admissible as affirmative evidence. Otherwise, as to those which by the courts are deemed works of exact science. The Northampton tables fall within this class." There is an old case in the superior court, where the plaintiff sued for injuries to a horse, in which it was held that the well-known work called "Youatt on the Horse" was erroneously received in evidence, and in a comparatively recent case the general term of the fourth department reversed a judgment because extracts from medical books were read to the jury. There are not many cases, however, in the law reports of New York State bearing directly on this point, as the consensus of opinion is that there have been too many erroneous dogmas of both law and medicine to establish the justice of any decision.

New Periodicals; A Protest.—Nine new German medical periodicals were announced in the last months of 1897, and medical literature in other countries is almost equally prolific. Von Düring writes to the *Deut. Med. Woch.* protesting against

this multiplication of professional organs and a waste of energy time and money, rendering it impossible for any one to keep an intelligent oversight of medical literature. "Each new journal," he says, "contains possibly one or two important articles during the year, but these might just as well have been contributed to some established journal. The rest of the contents: news, abstracts, etc., are found almost simultaneously in all the leading established journals." He therefore appeals to his confrères not to allow themselves to be cajoled into lending their name and prestige or contributing to these sprouting journals. If they will take Punch's advice to those about to marry: "Don't!" they will save the rest of the profession much time and money, while maintaining the dignity of science, which will inevitably be impaired by the "Vielschreibererei" necessitated by a host of new periodicals. And the new publications, refused the name and support of prominent members of the profession, would "die a-borning."

Rush Monument Fund.—Dr. William H. Humiston, president of the Ohio State Medical Society, has appointed the following special committee to raise Ohio's promised contribution to the Rush Monument Fund: Drs. William E. Bruner of Cleveland, E. W. Mitchell of Cincinnati, S. S. Halderman of Portsmouth, N. R. Coleman of Columbus, C. N. Smith of Toledo. This divides the State into five natural districts, and it is hoped that funds will promptly be forthcoming to show that Ohio will be second to no other State in honoring the great American physician of a century ago, who was a signer of our Declaration of Independence. Subscription lists will be promptly opened and the profession at large will be appealed to directly. Those who feel disposed to subscribe even a little to this worthy object should at once communicate with the nearest member of the committee. It should be borne in mind that our homeopathic brethren have raised between \$75,000 and \$100,000 for the monument to Hahnemann in Washington. Shall we publicly say we can not do as much?—*Cleveland Jour. of Med.*, February.

Effects of Modern Projectiles in Warfare.—The *Medical Press and Circular* (January 19), commenting on "Gunshot Injuries in the late Greco-Turkish War," a paper published in the *West London Medical Journal*, by Henry J. Davis, says: "Practically, only three kinds of rifle bullets were employed in the war. The Greeks used the Le Gras French rifle, with a Chassepôt lever action, and the Turks were armed chiefly with the Martini Henri, while some of the Turkish brigades had the German Mauser magazine rifle. But Mr. Davis never came across a single wound in which a Mauser bullet had become lodged. He accounts for this by stating that the terrific velocity of this bullet—it is effective at 4000 yards—is such that it passes through everything, soft parts and bones, and does not remain in the body. In consequence of this the wounds which it inflicts are much less severe than those caused by the Martini bullet, which, on the other hand, usually splinters a bone in all directions. The use of X-rays was found of service in detecting the presence of bullets. . . . In reflecting upon the facts to which attention is drawn in this paper, it would seem fair to assume that modern projectiles tend more to disable a soldier than to kill him: that is to say, he runs more chance of receiving a slight disabling wound than of being killed by a more severe one. Again, in taking into consideration the chances of life after even a severe injury, it should be remembered that these are much greater than has ever been the case before. The resources of modern surgery are such that if a man be not killed outright, the chances for the most part are all in his favor that his life will be saved. However, it would not be possible to make any forecast of the results of the killed and wounded in the next great European war: the probability, perhaps, is that the proportion of wounded would be very high, but this would doubtless largely depend upon how the troops were maneuvered, and the nature of the work which they were called upon to carry out. But with such weapons of precision now forming the 'slaying machines' of modern armies, everyone with humane feelings will earnestly hope that it will be long before the opportunity for testing these machines will arise."

Societies.

The following recent meetings are noted:

Illinois.—Chicago Medical Society, February 23 and March 2.

Iowa.—Scott County Medical Society, Davenport, February 14.

Maryland.—Baltimore County Medical Society, Baltimore, February 17.

Michigan.—Wayne County Medical Society, Detroit, February 17.

Missouri.—St. Louis Medical Society of Missouri, February 26.

Ohio.—Belmont County Medical Society, Bellaire; Lucas County Medical Society, Toledo, February 18; Muskingum County Medical Society, Signal, February 23.

Wisconsin.—Kenosha County Medical Association, Racine, February 18.

Louisville.

Jas. F. W. Ross of Toronto was the guest of Dr. E. S. McMurtry recently. A dinner was given in his honor by his host, to meet a number of the local profession. With the following he has gone to New Orleans for a brief visit: Drs. C. A. L. Reed of Cincinnati; J. M. Mathews, H. Horace Grant, Thos. Hunt Stucky and L. S. McMurtry. While in New Orleans the party will be specially entertained at Tulane University.

SMALLPOX.—In the southeastern part of the State at Middleboro, there has been a severe epidemic of smallpox, affecting mostly, however, the negroes and poorer whites. There have been a number of cases and the epidemic does not seem in the least abated. The Secretary of the State Board of Health has submitted a report of a personal observation to the Board and to the Governor. The Board has issued a circular of instructions requesting that everybody be vaccinated at an early day.

Detroit.

AT THE DETROIT MEDICAL AND LIBRARY ASSOCIATION, February 21, Dr. A. M. Phelps of New York, held a clinic under the auspices of the Association at Harper Hospital before the members of the medical profession of this city, and demonstrated the technique of the Phelps's operation. Three cases of club-foot were treated. The first case was that of talipes varus in a child of 5 years. The second was that of a young lady of 16 years suffering from double talipes equinovarus. She had been operated on four or five times by multiple tenotomies. The tendo Achillis had been cut across at the usual point twice, and a high tenotomy had been made close up to the commencement of that tendon. There were scars on the inner side of the foot showing other tenotomies. The third case was that of a child only two months old with double talipes varus. The doctor laid great stress on the importance of thorough division and open incision. He pointed out that the inner side of the foot was much shorter than the outer side, and advised manipulation of the foot to bring the tendo Achillis upon the stretch and quite tense, then the puncture should be made with a sharp-pointed tenotome and the section completed with a blunt instrument; then with the force required bring the heel on a level, or preferably below the level of the sole of the foot; then put the fascia, the muscles and tendons all upon the stretch and make an incision from a little in front of the internal malleolus obliquely downward, making the division of sufficient length and depth to bring the foot into the normal position. The doctor does not stop at the division of the abductor pollicis, flexor brevis, internal lateral ligament, or even artery and nerve if impossible to avoid. Dr. Phelps claims that while his operation is radical, it is the only operation after which relapses do not occur: that he has not had gangrene or sloughing from any of the 700 and more operations he has performed, and he has operated on patients all the way from a few days old to up to those of 58 years.

AT THE REGULAR MEETING of the Wayne County Medical Society held on the evening of February 24, Dr. J. A. Clark read a paper on "Anomalies of Albuminuria," presenting the theory that not only are there numerous cases of Bright's dis-

ease without albuminuria, but that there are examples of cases of albuminuria who even have a few casts in the urine, and are yet free from renal disease. The Doctor cited the histories of several cases in his own practice to bear out his proposition.

Washington.

REPORT OF THE HEALTH OFFICER.—The report of the health officer for the week ended February 19 shows the number of deaths to have been 125, of which number 73 were white and 52 colored. The principal causes of death were: Diseases of the nervous system, 15; circulatory, 14; respiratory, 47. There were 2 fatal cases of diphtheria, 3 of typhoid fever, 2 of whooping cough and 1 from la grippe. At the close of the week there were 45 cases of diphtheria and 42 cases of scarlet fever under treatment.

MEDICAL SOCIETY.—At a meeting of the society held on the 21st inst., the Committee on Public Health made a report on "The Water-Supply and Sewerage of Washington and Reclamation of the Anacostia Flats." The meeting was called to order by the president, Dr. S. C. Busey, who gave a résumé of the work done by the society and his Committee of the Board of Trade toward securing legislation for purification of water and sewage disposal; he also referred to the valuable scientific work done by the society in this connection. In closing he said: "All these efforts have been futile and the city remains today the prey to a single preventable disease which has cost its citizens in loss of life and actual outlay in the last ten years more than would have been required to complete the systems of water extension and purification and sewage disposal." Dr. G. W. Johnston, the present chairman of the Committee on Public Health, submitted a partial report of the work done by his committee. He discussed water-supply and filtration from a scientific and financial point of view. Among other things he said: "The Potomac River, above the take-in, is one vast sewer for the reception of all sorts of industrial waste, and the offal and sewage of comparatively large communities. The distance is such that it is to some extent diminishing these dangers. We find that in the past seventeen years 2539 persons died in Washington from typhoid fever, making an average of 145.35 per year." The discussion was made further valuable and instructive by the remarks of Drs. George M. Kober and Kinyoun. The subject was continued for discussion at the next weekly meeting of the society.

Cincinnati.

THE MORTALITY REPORT for the week shows: Stillbirths, 7; zymotic diseases, 10; phthisis pulmonalis, 14; other constitutional, 13; local, 63; developmental, 7; violence, 5; total, all causes, 112; annual rate per thousand 14.38; preceding week, 122; under one year, 23; between one and five, 10; corresponding week, 1897, 101; 1896, 148; 1895, 128.

THE damage suit against Dr. C. D. Palmer as the result of his leaving a part of a broken needle in the abdominal cavity of a woman was last week decided in favor of the Doctor. The defense was that Dr. Palmer exerted every effort to find the broken point of the needle and only gave up the search when the anesthetizer warned him that the patient was in such a condition that it was not safe to further prolong the administration of the anesthetic. The needle, when found by another operator some time after, was completely encysted.

At the Academy of Medicine Dr. B. F. Lyle presented a paper entitled "What Treatment Shall we Adopt for Pulmonary Tuberculosis?" The author reviewed the various methods of treatment and as to the prognosis said that as a general rule patients who improve in weight and whose temperature is never above 100, offer hope of recovery, while in those whose temperature never exceeds 99, we may feel almost positive of success. The author has failed to obtain satisfactory results from either tuberculin or a solution of nuclein, and he claims that the nutrition is the foundation of the reparative process. The indispensable value of the open-air life is shown by

the experiments of Trudeau, who successfully inoculated rabbits with bacillary matter. Some were allowed their freedom and others confined. The former recovered without any trace of the disease remaining while all the latter died. In thirty-eight cloisters in France, of 2099 deaths 1320 were from tuberculosis, a percentage of 62.88. In the Alabama Insane Asylum, 28 per cent. of the whites and 42 per cent. of the blacks succumbed. Of the persons confined the prisons of Austria, 60 per cent. died from tuberculosis, while but 15 per cent. of those living without perished from the same. In Denver, in 1896, sixty-four unimported consumptives who were living in unfavorable hygienic surroundings died. The importance of having the air-passages free and unobstructed was emphasized. The food selected should be rich in nitrogen, hence meats should be the staple article of diet. Alcohol is avoided, as its rapidity of oxidation leads us to suppose that the same criticism might be made of it as of cod-liver oil, viz., that its affinity for oxygen would result in deficient oxidation of the by-products of tissue metamorphosis. In large quantities its use is condemned as positively injurious, as it forms with the hemoglobin of the red blood corpuscles, a compound which takes up and parts with oxygen less readily than normal hemoglobin, thus leading to a general diminution of the metabolism of the body. It also exerts an inhibitory action on the formation and functions of the leucocytes and other corpuscular elements of the blood and tissues. The elimination of alcohol by the lungs also increases the bronchial catarrh; the heart's action is weakened through fatty degeneration; the nervous system is benumbed, and the numerous other functional and pathologic conditions produced antagonistic to the well-being of the patient. Of the medicinal agents usually employed, the author has found creosote of benefit in some cases, when it undoubtedly lessened the cough, diminished the secretion and aided in increasing the general nutrition. Iron, quinin and strychnia (the dose of the latter pushed to the physiologic limit) is recommended, while sponge baths, phenacetin and quinin should be resorted to as antipyretics. Bromid of potash in ten grain doses every two hours will often be found efficacious in controlling the harassing cough. Intratracheal injections have been very satisfactory and the following formula is recommended:

R. Mentholi	3.00
Camphoræ	2.00
Ol. eucalypti	3.00
Guaiacoli	0.50
Liq. alboleni	100.00

About 5 drams or 20 c.c. of this should be used. For troublesome night sweats agaricin in 1-10 grain doses is efficient.

HEALTH OFFICER WITHROW has presented his annual report in which he gives the total number of deaths during the year, 5,565. The annual rate per thousand being 13.7. As a result of the establishment of a city laboratory and more active quarantine and supervision of cases of diphtheria, the mortality has fallen from 23.8 in 1896 to 15.9 in 1897. The public markets have been much improved in their sanitary condition. The number of deaths from tuberculosis, 675, is a decrease of 62 over that of last year and is the lowest mortality of any year since 1878. This reduction is in a large measure due to the wider dissemination among the people of the belief in the contagiousness of the disease and the recent commendable practice of sending all tubercular patients from the Cincinnati Hospital to the branch hospital. The excellent work done in the milk department is detailed at length. A list of the houses in which infectious and contagious diseases are reported is sent each day to the Public Library in order that the books coming from such houses can be properly disinfected. As to the fumigation and disinfection of houses the Trillat autoclave apparatus for the generation of dry formaldehyde gas has been adopted and found the most satisfactory. The number of deaths from typhoid fever is 101, the lowest since 1879. The strongest plea is made by Dr. Withrow for the erection of an isolation hospital for contagious and infectious diseases of children, the boiling and filtering of all water used for cooking or drinking purposes; the instruction of the school teachers in the use of the clinical thermometer

and the first symptoms of infectious diseases in order that they may be able to detect cases before they have progressed far enough to compel the child to remain home; the closer supervision of the public dumps, and a greater number of parks or breathing spaces for the poorer classes.

CHANGE OF ADDRESS.

Chase, A. F. From Philadelphia, Pa., to Perryton, Ohio.
 Diemert, J. A. From 109 Ontario Street, to cor. St. Clair and Wilson Avenue, Cleveland, Ohio.

ORIGINAL ARTICLES.

AUTO-INTOXICATION IN ITS RELATIONS TO THE DISEASES OF THE NERVOUS SYSTEM.

Read before the Illinois State Medical Society.

BY DANIEL R. BROWER, M.A., M.D.

Professor of Mental Diseases and Therapeutics, Rush Medical College;
Professor of Mental and Nervous Diseases, Woman's Medical
School, and Post-Graduate School, Chicago, Ill.

We are at the beginning of a new era in the pathogenesis and treatment of the neural diseases. The discovery of the neuron has resulted in making clear some of the dark passages in physiology and pathogenesis, and the dynamic changes produced in these neurons by alcohol and other extrinsic poisons, that have been so marvelously demonstrated by Andriezen, Van Gieson and others, and the reasonable inference that intrinsic poisons are equally powerful in establishing pathologic conditions, open up a new line of important therapeutic investigation.

The primary form of the psychoses from the beginning has been called melancholia, "black bile," because of the relation ever recognized between mental depression and perverted action of the great viscus of the abdominal cavity, and in more modern times quaint old Abernethy emphasized the same etiologic thought when he gave utterance to the aphorism that the best medicine for the "blues" is the blue pill. That various nervous diseases are produced by alcohol, lead and other extrinsic poisons, and by the toxins of various infectious diseases, by uremia, by sunstroke and by experimental thyropravia is universally accepted, and moreover, the neuro-cellular lesions that are produced by some of these poisons have been demonstrated. Auto-intoxication includes the results of toxins that are produced within the body by normal and abnormal chemic activity, and those that follow from the suppression or disturbance in the functions of such organs as the thyroid and other glands that produce constituents necessary to healthy nutrition, and those toxins that are produced by germs in the gastro-intestinal tract and elsewhere about the body.

Albu suggests the following general classification of auto-intoxication:

1. Auto-intoxications from the suppression or disturbance of the functions of an organ, *i.e.*, auto-intoxication of thyroid gland, pancreas, liver, supra-renal capsules, producing myxedema, diabetes, acute yellow atrophy and Addison's disease, respectively.

2. Auto-intoxications which occur from anomalies in general metabolism without definite localization, such as rheumatism, gout and oxaluria.

3. Auto-intoxications which are caused by the retention of the physiologic products of metabolism in different organs, such as poisoning due to extensive

destruction of the skin by burning, carbonic acid poisoning, uremia and eclampsia.

4. Auto-intoxications due to the over-production of physiologic and pathologic products of the organism, such as ammonemia, acetonuria, diaceturia, diabetic coma, Basedow's disease, etc. The most frequent source of this intoxication is the gastro-intestinal tract.

In normal digestion we have ultimately elaborated absorbable products, soluble albuminoids, emulsified fat, glucose and maltose. In indigestion we have numerous aromatic, nitrogenous and acid compounds produced that are poisonous. In the stomach the absence or diminution of free hydrochloric acid results in putrefaction, and in this viscus and in the intestines the presence of micro-organisms result in decomposition, and among the resultant toxic products thus produced we have lactic, acetic, succinic, carbonic, the aromatic and the volatile fatty acids, indol, skatol, phenol, peptinatoin, ammonia, methan, sulphuretted hydrogen, methyl, mercaptan, etc.

The liver acts as a barrier to guard the organism against the invasion of these various poisons and may transform them into innocuous substances or eliminate them by the bile as non-absorbable chemic combinations. The skin, kidneys, bowels and lungs assist the liver in eliminating these products.

Bouchard¹ has demonstrated that the normal man manufactures enough of these several poisons each day to destroy the body if retained within it; he has separated from the urine of such a man, seven toxic substances, two of which will produce convulsions, one myosis, while one is antipyretic, one is narcotic, one is diuretic, and one is a sialagogue. The toxicity of the urine in the healthy man varies according to numerous circumstances, such as cerebral and muscular activity, sleep, diet, etc. The urines of sleep are usually less toxic than those of the waking state. The urotoxic co-efficient varies with disease; the urine of a uremic patient is not toxic, because the poisons which should be eliminated are retained. The urine in mania is less toxic and in melancholia more toxic than normal. The urine from a maniacal patient when injected into an animal will give rise to excitement and convulsions; that from a melancholiac to depression, restlessness and stupor.

Morgan² found abnormalities in the urine in 70.6 per cent. of the cases of insanity; such a high-specific gravity, albumin, excess of phosphates, urates, uric acid and oxalates.

Agrotini³ noticed the gastric disturbances, the hyperchloridity and the urinary toxicity with the epileptic attacks, and very wisely concludes that auto-intoxication from altered tissue change and digestive disorder has an important part in the mechanism of the attack.

Somers⁴ concludes that in all cases of insanity there is a deterioration of the blood, showing a diminution

of red corpuscles, an increase in white corpuscles, and a low percentage of hemoglobin; that cases of melancholia show the lowest amount of hemoglobin; the eosinophilic cells are absent in the majority of the cases, and that poikilocytosis is characteristic of this disease. That the eosinophilic cells are increased in mania, and that there is an intimate relation between an hypertrophied heart, sclerosed arteries, lowered blood nutrition and the course of mental diseases, and asks this important question, "Is it possible by the use of some drug where you increase metabolism to also increase the number of eosinophilic cells and thus free the system of the toxic influences which are supposed to be the cause of melancholia?"

Contributing to this toxemia of the brain is doubtless the peculiar arrangement of lymph channels around the blood vessels: the blocking of these channels, a pathologic condition not unreasonable, would result in auto-intoxication of this organ. The psychoses that are probably of auto-toxic origin are the manias, primary melancholias, whether acute, subacute, or chronic. The nervous diseases that have probably the same origin are neurasthenia, epilepsy, tetany, chorea, exophthalmic goiter, disorders growing out of rheumatism and gout, and probably many others.

Van Gieson⁵ has demonstrated, in these toxemias, an acute parenchymatous degeneration of the neuron from which recovery, both of structure and function, may take place, provided the poison acts only for a brief period, but if the action continues, the degenerative changes eventuate in the irreparable destruction of the cell.

The gastro-intestinal tract is the theater of the most important of the operations of auto-intoxications, and the first important factor is dilatation of the stomach. Bouchard⁶ has most graphically described the consequences of this pathologic condition, and it is unfortunate that our means of diagnosis in these cases are so meager. The second important factor is intestinal indigestion, and the third is coprostasis. The urine will often give important aid to diagnosis, and it should be tested for indican and the total sulphates, and will show increased ratio of the former and diminished ratio of the latter, although ethereal sulphates will be increased in auto-intoxication.

The treatment of these cases must consist in the treatment of the pathologic condition associated with it. First to be considered is the treatment of gastrectasis, and, in this, diet is of the first importance. The food must be very digestible, concentrated, so as to give least taxation to the motility of the stomach. The meals should be taken three times a day with the longest possible interval. It is necessary to avoid, as much as possible, everything that can have a tendency to undergo fermentation. Alcohol, which furnishes acetic acid, especially red wines, beers, tea, coffee, carbohydrates and fat are objectionable. The best diet would be a predigested one, peptonized milk, malted milk, somatose, especially the combinations of malted milk and somatose. The best dietary is an animal one, tender beef, mutton, fowl free from fat, eggs, fish, the smallest possible allowance of bread, peas, asparagus, tomatoes, peaches, grapes, apples and but very little water, and this should be taken hot before meals. If hydrochloric acid is deficient in the stomach contents, as it usually is, then hydrochloric acid may be administered after eating. It is without doubt the best of the stomach antiseptics; with this

may be administered the simple bitters. Strychnia is also a drug of great value, because of its power to restore tone to the debilitated muscular fiber. The intragastric application of faradism, the cutaneous use of faradism and of static electricity, all alike stimulate peristalsis and promote the nutrition of the muscular coats of the stomach. Abdominal massage is also of service. Lavage is necessary in all of these cases, and it should be used daily; it can best be performed a half hour before breakfast, or dinner. The red-gum soft-rubber tube, with funnel attached, is the simplest and best apparatus; the patient can soon be taught to use it himself. The water should be warm, and with some mild antiseptic, such as sodium borate, sodium salicylate, or such as may be preferred. About a pint should be introduced at a time, and then this should be siphoned out and followed by another and another until it returns clear. It may be necessary to change the climate: a high altitude for some, a sea level for others, with freedom from care, distraction by travel, or some pleasurable occupation.

The treatment of intestinal dyspepsia calls first for purgatives, and the salines meet the indications best. The combination of sodium sulphate with sodium phosphate, four parts of the first to one part of the second, is an admirable one. The best intestinal antiseptics are beta-naphthol, benzo-naphthol, bismuth salicylate and guaiacol carbonate. Of this valuable series benzo-naphthol is probably the best, because it is but little toxic and does not irritate the kidneys. It should be administered in $\frac{1}{2}$ gram doses, four times a day.

Colonic impaction is a very frequent condition in chronic invalids and is very frequently overlooked. For its relief cathartics are not sufficient. Colonic flushing, in the knee-breast position, with normal saline solution at body temperature, with abdominal massage, must be used. The flushing will frequently have to be repeated several times before the accumulations are removed. It should be followed with aloetic laxatives and intestinal antiseptics. As a rule, all of these cases of auto-intoxication will require hematinics, Bland's mass, freshly prepared, combined with extract nux vomica and arsenic, have given me the best results.

The treatment of Albu's first class of auto-intoxications, of those due to the suppression or diminution of the secretions of some gland, suggests the question of organo-therapy, and I think we may say that the great expectations of this new therapy have not been realized. Spermin, cerebrin, medullain, cardain and all such have failed to produce the results promised; but thyroid, bone marrow and nuclein have in some cases given results that are surprising. No one can dispute the value of thyroid extracts in myxedema, cretinism, acromegaly, obesity, tetany, rosacea, ichthyosis, scleroderma, some forms of syphilis and some forms of insanity, especially the adolescent, climacteric and puerperal cases. The value of red bone marrow in certain cases of anemia seems well established, and the nucleins seem to have the power of increasing the bactericidal capacity of the blood and in anemia following infectious diseases: in gonorrhea and in tuberculosis, benefit has sometimes been obtained.

CONCLUSIONS.

1. Some of the nervous diseases are the product of auto-intoxication.
2. This autotoxis produces a parenchymatous

degeneration of the nervous system, acute or chronic, that may result in the destruction of the structure and function of the nerve cells. (Van Gieson and Andriezen.)

3. The peculiar arrangement of the lymph channels in the nervous system makes auto-intoxication of the brain possible by the blocking of these channels.

4. The principal factor in this autotoxis is a disordered gastro-intestinal tract.

5. Gastrectasis, intestinal dyspepsia and coprostasis are ordinary conditions producing gastro-intestinal intoxication.

6. The diagnosis is to be made; *a*, by a regional examination; *b*, by examination of the gastric contents, and *c*, by examination of the urine.

7. The urines will show increased amounts of indican, diminished total sulphates, and an increase in the amount of ethereal or conjugate sulphates.

8. There will also be found, usually in consequence of this autotoxis, a diminished hemoglobin record and a diminished number of red blood corpuscles.

9. The treatment should consist of lavage, enterocolysis, gastric and intestinal antiseptics, laxatives and hematinics.

SURGICAL TREATMENT OF GASTRIC ULCER.

Read before the Iowa State Medical Society, 1897.

BY VAN BUREN KNOTT, M.D.

ST. LOUIS CITY, IOWA.

Surgical interference for the relief of the ulcer of the stomach and its complications, although of comparatively recent date, has by the brilliancy of its results become a well established procedure and promises much for the future. In considering its applicability I shall be as brief as possible, dwelling only on those conditions in which it has been proven of unquestionable value. Although the radical cure of gastric ulcer has been advocated, and attempted by excision of the ulcer itself, the results have not as yet justified the adoption of this measure as the routine treatment for this condition, nor is it warranted by statistics, as according to Welch about 85 per cent. of all cases of ulcer of the stomach heal spontaneously.

Therefore, I shall in this paper consider the value of surgical interference in those cases of gastric ulcer complicated by one or more of the following conditions: Perforation, hemorrhage, cicatricial contraction and adhesions to neighboring viscera or the abdominal wall.

Perforation of a gastric ulcer is always a very serious accident and in the majority of cases the only hope for the recovery of the patient is offered by surgery. If the perforation occurs rapidly and into the general peritoneal cavity, no time having been afforded for the formation of limiting adhesions, the patient unless relieved by surgical intervention rapidly succumbs to acute septic peritonitis.

In these cases the surgeon should never hesitate, as experience has demonstrated that the successful cases are those in which the operation was performed within a few hours following perforation. Delay can mean nothing but a rapidly fatal infection.

An incision should be made in the median line between the umbilicus and the sternum, and if the stomach is not then readily accessible another incision at right angles to the first will render it so. First, locate the position of the perforation and effect its closure before attempting to remove the extravasated gastric contents.

In by far the greater number of cases closure may be best effected by turning in the peritoneal edges and retaining them in position with Lembert sutures. In some cases, owing to the diseased condition of the stomach wall, a large portion of it may require inversion. Again, a portion may be resected and the opening closed. It is extremely fortunate that perforation of ulcers of the anterior wall of the stomach is much more common than of those situated on the posterior, as in the latter case the perforation is accessible only with the greatest difficulty, if at all.

As soon as the perforation has been closed, the peritoneal cavity must be carefully cleansed of all extravasated matter, first, by dry gauze sponging and then by irrigation with large quantities of normal saline solution. Irrigation, as frequently practiced, employing three or four quarts of fluid, is worse than useless, as with such a small quantity the extravasated particles are only disseminated throughout the peritoneal cavity and not washed out. In all cases, gallons of hot normal salt solution should be used.

Following the irrigation, the peritoneal cavity should again be sponged dry and ample gauze drainage provided. If evidences of general peritonitis are already present it is well to supplement the ordinary drainage with gauze wicks placed at the most dependent portions of the cavity and carried out through incisions in the loin.

M. H. Richardson¹ has collected forty-four cases of operation for this condition, with ten recoveries. When we consider that all these would have died without operation, these results are gratifying. The same observer also states that the percentage of recoveries during the last two years was much larger than in those cases operated on before that time, indicating that the results are improving with experience.

Sometimes perforation of a gastric ulcer occurs so slowly that time is allowed for the formation of limiting adhesions and we have a localized abscess resulting. This abscess may be superficial deep or sub-diaphragmatic. Weir² urges that left-sided pyoneumothorax with a previous history of gastric symptoms should be suspected as due to a perforated ulcer of the stomach. These abscesses should be freely opened and drained, following the technique employed in pelvic or abdominal abscesses due to other causes, and the perforation closed in the usual manner. Cases have been reported in which perforation was followed by neither general peritonitis nor localized abscess, and a complete spontaneous recovery was made, but such a fortunate termination is extremely rare.

Again, adhesion has occurred between the stomach wall and a neighboring viscus or the abdominal wall before perforation has occurred, the ulcer being thus provided with a new floor and infection prevented. The resulting adhesion, however, may occasion so much functional disturbance and pain as to necessitate an operation for its relief.

The abdomen should be opened, the adhesion found and separated and the opening into the stomach closed

¹ Deonils' System of Surgery, Vol. iv.

² Annals of Univ. Med. Science, 1893.

as indicated above. The following case illustrates this condition and is interesting from the fact that the adhesion was separated without re-opening the ulcer.

Case.—E. J., a female aged 32 years consulted me regarding severe gastralgia and digestive disturbance of about one year's duration. She complained of very acute abdominal pain coming on soon after eating, which was frequently attended with vomiting. Coughing, sneezing, etc., were attended by the most excruciating pain. She had been constantly under treatment for one year, her ailment being diagnosed as dyspepsia, and was almost discouraged concerning her condition. Owing to the difficulty with which food was retained in the stomach, she was extremely emaciated. Temperature was 100, pulse 85. An examination of the abdomen revealed, upon palpation, a tender indurated spot about one-half an inch above and the same distance to the left of the umbilicus. This, together with the symptoms above enumerated, led to the diagnosis of an adhesion between the stomach and the abdominal wall, with possibly the formation of an abscess. In addition to the usual preparations for the celiotomy, the stomach was thoroughly washed out. The abdomen was opened in the median line and the adhesion existing between the anterior surface of the stomach and the abdominal wall was readily found. This point was walled off from the surrounding tissues with gauze sponges and the adhesion separated, keeping close to the abdominal wall. No pus was present and the stomach wall at this point was found to be intact, the ulcer having apparently healed. The ulcerated area, however, was folded in and retained by close suturing. As no abscess existed and the stomach had not been opened the abdominal incision was closed without drainage. The troublesome symptoms immediately disappeared and, fifteen months after operation, had not recurred. The patient rapidly regained her lost weight and has since been in perfect health.

The interesting features of this case are:

1. That the ulcer should have occasioned such extreme functional disturbance and established so firm an adhesion without being attended with hemorrhage and more of the classic symptoms.

2. That after so active an ulcerative process the lesion should undergo such complete spontaneous healing that the operation revealed practically no trace of it except the adhesion and a slight induration of the stomach wall.

3. That the condition was easy of diagnosis owing to the induration which could be plainly felt and the typical disturbance of function. (Most authorities state the existence of adhesions between the stomach and contiguous structure can only be surmised without an exploratory incision.)

If, during the course of a gastric ulceration, alarming hemorrhage should occur and death seems imminent from this cause, the abdomen should be opened, the ulcerated area excised and closure effected by suturing. If for any reason this can not be accomplished the stomach must be opened and the bleeding vessel ligated.

Cicatricial contraction accompanying the healing of a gastric ulcer does not usually occasion enough trouble to demand operative relief unless the ulcer is situated at the pylorus. Contraction and cicatrization occurring at this point may, by occluding the pyloric orifice, occasion the troublesome train of symptoms consequent upon the dilatation of the stomach which ensues.

Should this occur surgical intervention is imperative. Several procedures have been advocated for the relief of this condition, but I think we may adopt pyloroplasty, as performed by Heinecke, as the operation of election and I can not conceive of a pyloric stenosis due to the above cause in which it would not be applicable.

In all operations on the stomach strict adherence to the following points is essential.

If the case be one demanding immediate interference, the feeding of the patient should be so regulated that at the time of operation the stomach will be empty and by copious irrigation the intestine rendered as free as possible from fecal matter.

Just before operating, the stomach should be thoroughly washed out. After the stomach is exposed, if perforation exists, and extravasation has occurred, before attempting to remove the extravasated material the opening in the stomach must be found and closed. The escaped stomach contents may be best removed from the peritoneal cavity by dry gauze sponging followed by copious irrigation with normal salt solution and the cavity again sponged dry.

If extravasation has not occurred such an accident must be prevented by immediately surrounding the operative field with sponges walling off the general cavity of the peritoneum.

In those cases where the perforation occurs upon the posterior wall of the stomach and is inaccessible for suturing, further extravasation must be prevented by carefully placed gauze packing. The writer has encountered such a condition twice in gunshot wounds of the abdomen.

In all cases where extravasation has occurred ample gauze drainage must be provided and if evidence of general peritonitis is present, counter openings for drainage in the loin are indicated.

Drainage must be maintained according to the requirements of individual cases. There can be no fixed rule regulating its withdrawal.

Great care must be exercised during the evacuation of a localized abscess following perforation, that its limiting walls be not broken and a general infection invited. It is recommended that these cavities be cleansed by dry sponging, as the force of an irrigating stream is dangerous.

In separating adhesions between the stomach and neighboring parts by dissection, strive to avoid opening into the stomach cavity.

If after separation the adherent area of the gastric wall appears weak, turn it in and suture.

For stomach wounds in general, the best suture, is an interrupted Lembert of fine silk. In these operations time is an important consideration and they should be rapidly performed, every detail being carefully arranged before making the incision. The after-treatment of all operations upon the stomach is of great importance. Nothing should be allowed by the mouth until the third or fourth day, all nourishment being administered by rectum. Mouth feeding when begun should be done with great care for some time, soups and broths being first given.

THE CONSERVATIVE AGENCY OF SHOCK.

Read at the meeting of the Western Surgical and Gynecological Association, at Denver, Colo., Dec. 28 and 29, 1897.

BY H. G. WETHERILL, M.D.

PROFESSOR OF GYNECOLOGY, UNIVERSITY OF DENVER.

Until recently, the old notions and teachings of the cause and modus operandi of surgical shock have been little modified, notwithstanding the vague and uncertain theories upon which they were based. Literally, the term surgical shock has been applied to the condition of the body which is induced by severe injuries, operating through the nervous system, not attended with or produced by hemorrhage. Profound depression and even death may be so caused, but not com-

monly, and even when so produced, that it is serious because of the nervous disturbance alone can not be admitted, as the secondary circulatory disarrangement is the prominent symptom presented and is also the symptom which must be combatted with the greatest vigor if the life of the patient is to be saved.

Few serious injuries or surgical operations, which are followed by so-called shock, are unattended by hemorrhage, external or concealed. The symptoms which such patients present are due to the conjoined effects of the hemorrhage and "shock" combined.

For many years it was taught that penetrating wounds of the abdomen and amputations through the hip joint were ordinarily fatal because of the profound shock which accompanied them, but later experiences have taught that with perfect hemostasis their mortality may be greatly reduced. This indicates that hemorrhage is a far more important factor in the production of what we have heretofore called shock than has been believed.

It has been usual to attribute the death of patients, upon whom abdominal operations have been performed, to the "shock" of the operation, while the autopsy has ultimately shown that the patient had died of concealed hemorrhage.

A small concealed hemorrhage may go on so slowly and insidiously as to give rise to none of the symptoms which are characteristic of hemorrhage as in contra-distinction to "shock." In such cases it will be difficult to say that the state is not one of literal shock.

The tendency now is to regard surgical shock, as a condition which follows such operations or severe injuries as exhaust the nerve force of the patient and reduce his blood pressure, through the true shock and the reflex action of the hemorrhage, the latter being considered the more important factor.

The present status is unsatisfactory and confusing and the definition and meaning of the term shock should be applied to the condition as it is now known and its double origin recognized; or if it be preferred to retain this term for its original and literal use it should be limited strictly to this meaning and some new word chosen for the description of the mixed condition which comes after injuries and operations, the genesis of which is due to both shock and hemorrhage.

The term traumatic asthenia is well suited to the description of this mixed condition and also indicates its origin.

This mixed shock has heretofore been regarded as a serious and unfavorable complication of injuries and operations. This view should also be reconsidered and modified as it is now believed, by some, that the condition is essentially conservative in its agency, that if it were not for this lowering of the vital action through and by the intervention of the reflexes the suffering of the patient would be far greater and his life more quickly sacrificed.

Recall the picture of profound shock often seen in the emergency operating room after injuries received on the railroad or in the factory. The patient is pale, with pupils dilated but with eyes closed, his skin is cold and clammy, he is pulseless or nearly so, his temperature is subnormal and he desires to be left alone and allowed to rest. He is not suffering in proportion to the severe character of his injury and is bleeding very little, not because he has no blood to lose but because it is not circulating with its usual force. Is it not evident that the conservative efforts of all nature's

agents are being exercised to render his suffering and the consequent exhaustion as little as possible, and prolong his life to the full limit by lowering his blood pressure and storing the vital fluid in his dilated and relaxed blood vessels? His very condition of perfect relaxation, inability and disinclination to make exertion is his salvation.

In all diseases, under all circumstances, the tendency of the natural processes is to resist death and destruction as long as possible and by every means.

The successful treatment of disease must take into consideration the indication nature gives as to the best way to proceed. Success depends upon following these indications and supporting the resisting powers in the fight for life, for death comes not by nature's consent or assistance but always in spite of her strongest antagonism.

I believe it has not been proved by the experimental physiologist that the reflex effect of hemorrhage is to lower blood pressure and so save blood volume. That this result is attained every surgeon knows, but to what extent it is accomplished through reflex action we can not say.

The experience of every surgeon who has carefully observed the condition of his patient under and after operation will lead him to believe that there is some controlling influence exercised over the heart and the circulation of the blood by a persistent arterial hemorrhage however small in amount. The influence upon the circulation is out of all proportion to the amount of blood lost as is also the profound effect in general upon the patient, who becomes cold, pulseless and is evidently near death, perhaps to be perfectly revived, with a full bounding pulse, when the hemorrhage is arrested. Such phenomena are sometimes seen in cases of ruptured ectopic pregnancy, the patient's condition becoming decidedly better or worse with each arrest or fresh attack of hemorrhage. It hardly seems rational to doubt that these remarkable effects are the results of reflex action, or that even a small but persistent hemorrhage may induce them.

Gynecologists and abdominal surgeons are peculiarly interested in having this matter thoroughly understood, for to them the question must often come for solution whether a patient is suffering from shock or it be traumatic asthenia, with the possibility that hemorrhage is still persisting and so maintaining through its reflex effects the state of lowered vitality. The importance of this question in its bearing upon treatment is evident. If the case be one of uncomplicated shock cardiac and other stimulants are indicated, transfusion and infusion may be employed and all the vital forces be quickly brought into normal activity; whereas if concealed hemorrhage continues these remedies are contra-indicated and opposed to the conservative efforts of nature, for the more the circulation is increased in force and volume the greater must be the hemorrhage till all bleeding points are controlled.

That the balance should be in every case so nicely adjusted as to give exactly the required amount of protection is too much to expect. It must be clear that the shock or traumatic asthenia may under certain circumstances be so severe and profound that the patient can not react and recover.

Here as in other branches of medicine the personality and condition of the patient bear directly upon the result. The nervous, anemic, exhausted, old, or very young person will not withstand a degree of trau-

matism that would make little impression on one in the full vigor of youth.

The degree of surgical anesthesia and the length of time it is maintained must also affect the result through the obliteration of the reflexes and the consequent paralysis of nature's conservative mechanism.

The conclusions I deduce from the foregoing are:

1. Surgical shock entirely unassociated with hemorrhage is a condition rarely seen and one which may usually be successfully treated in persons who are otherwise in good health.

2. Hemorrhage though small in amount is a far more important factor in the production of surgical shock (as it is seen clinically) than we have been accustomed to think it.

3. This mixed shock (traumatic asthenia) should be designated by some distinctive title, or the term shock be construed to comprehend all the factors in its genesis.

4. While not proven it seems probable, that the effects of even a small continuous arterial hemorrhage is to produce through its reflex action lower blood pressure and in general a condition so like true shock as to be very difficult of differentiation, particularly if the hemorrhage is concealed; as in ruptured ectopic pregnancy.

5. Surgical shock, with or without hemorrhage, must be construed as primarily conservative in its tendencies. The incident prevention of rapid exhaustion, of acute suffering, or great blood loss when the blood vessels are opened, all tend to the ultimate saving of life.

6. Premature stimulation in the treatment of traumatic asthenia may defeat this conservative effort of nature. Bleeding should be stopped and proper provision made for the comfort and welfare of the patient before strong stimulation is resorted to, unless there is imminent danger of death.

7. Anesthetics must be sparingly and carefully given to patients suffering from surgical shock (traumatic asthenia), chiefly because they completely obliterate the reflexes. The saturation of the patient with an anesthetic may turn the scale against him even though the direct effect of the anesthetic be stimulant. The same rule holds good in regard to the employment of alcoholic stimulants if too freely used.

8. We should co-operate with and supplement nature's conservative efforts. They are always exercised in behalf of the patient, never against him.

212 McPhee Building.

LUPUS VULGARIS EPITHELIOMA—ACNE —ALOPECIA CIRCUMSCRIPTA—TINEA VERSICOLOR.

A Clinical Lecture to Members of the American Medical Association,
delivered in the Medico-Chirurgical Hospital of Philadelphia,
June, 1897.

BY JOHN V. SHOEMAKER, M.D., LL.D.

PROFESSOR OF SKIN AND VENEREAL DISEASES IN THE MEDICO-CHIRURGICAL COLLEGE AND HOSPITAL OF PHILADELPHIA.

LUPUS VULGARIS.

The patient is 40 years of age. The disease from which she suffers began about three years ago upon the right cheek, whence it has spread toward the upper lip. There is much infiltration in the affected part, and exterior to the edges of the main patch are a number of tubercles of glutinous appearance. These tubercles project slightly above the general surface.

The extensive and continuous patch upon the cheek is the result of the coalescence of many tubercles. Most of the cheek has been invaded in this manner. Upon the seat of disease are many fine scales. The development of these lesions has, from the first, been accompanied by considerable pain.

But the disease is not in active progress in all parts. Upon the cheek are several cicatricial spots. I know, therefore, that however chronic, disfiguring or deep this ulceration, it can not be of malignant character. Epithelioma never exhibits these cicatricial spots intermingled with slow, progressive ulcers. These features, in connection with the intact tubercles along the principal lesion are characteristic of lupus vulgaris. In other words, in lupus vulgaris we usually perceive coincidently different stages of the malady. The primary lesion is a papule or tubercle, deeply imbedded in the corium and visible at first as reddish, brownish or yellowish spots. The lesions are due to an infiltration of small cells, which in time undergo fatty degeneration and may be absorbed. In other spots ulceration occurs and may continue indefinitely or may cicatrize in certain spots. Now, all this process of evolution, involution, ulceration and cicatrization constitutes a totally different clinical picture from that of epithelioma. Upon an attentive study of cases we should rarely err in diagnosis. This is a typical case of lupus, but there are inveterate cases in which ulceration penetrates to or even involves the bone and such are very apt to be mistaken for cancer.

In this patient the butterfly arrangement of the lesions is absent, as indeed it generally is in lupus vulgaris. That symmetry of outline is far more indicative of lupus erythematosus. The age at which the patient was attacked is also exceptional.

In some cases the infiltration involves the papilla of the skin, which become immensely enlarged and sprout forth as wart-like elevations. This form of the affection is known as lupus verrucosus. Lupus generally attacks the face, though it sometimes appears upon other parts of the body.

The etiology of this disease has been the theme of much discussion. It is now looked upon by some as an attenuated form of cutaneous tuberculosis, although it is admittedly of a different clinical type from other forms of tuberculosis and the lesions contain few bacilli. As a general rule, the subjects of lupus enjoy fairly good health. In some instances they develop pulmonary tuberculosis.

Lupus vulgaris is liable to be mistaken for the tubercular or some of the ulcerative lesions of later syphilis. The former, however, is usually limited to the face. The tubercles of syphilis appear upon various parts of the body and display a characteristic coppery color. The ulcers of lupus have a tendency to coalesce; those of syphilis are most often isolated. Syphilitic ulcers are attended by abundant foul supuration and covered by greenish crusts. Syphilitic ulcers are more rapid in their course than those of lupus and the cicatrices of syphilis are white and smooth. Lupus scars are an unsightly disfigurement.

The treatment of lupus depends much upon the general condition of the patient. The food should be digestible and nutritious. If scrofulous or tuberculous manifestations are present appropriate remedies should be ordered. Other impairment of the system must be treated upon general principles. Cod liver oil is an excellent remedy and shall be given in this case. The patient feels weak although she has not

lost much flesh. She shall also be placed upon arsenic in the form of sulphid, beginning with 0.006 ($\frac{1}{10}$ grain) and running up to 0.016 gram ($\frac{1}{4}$ grain) three or four times a day.

I do not favor harsh local measures, as I have known them to be followed by systemic implication. An effective application to the lesions is pure liquefied carbolic acid, used twice a week. In the interim a weak carbolic acid ointment may be kept upon the parts.

EPITHELIOMA.

Our next patient is a man, aged 68 years. He also has an ulcer upon the cheek. This lesion is about the size of a five cent piece, of a nearly circular outline with hard, everted edges, of dark red and granular surface. It is the seat of much pain and bleeds upon slight provocation. Some thick, yellowish secretion covers its surface. It has been in existence for seven months and in the beginning had the appearance of an innocent wart, as far as the patient could judge.

These seeming warts, these dry fissures surrounded by a thickened and hardened nodule, are always suspicious matters in people above 60 years of age. We have here an epithelioma. It is of the utmost importance to recognize this disease at an early moment. If allowed to progress it will infallibly contaminate the blood and proceed to a fatal termination. Yet, of all the forms of cancer, cutaneous epithelioma is the most amenable to early and judicious treatment. We may excise the growth *in toto*, together with a large surrounding area of healthy tissue; we may destroy it by chemicals or electricity. We may seek to attain the same object by the interstitial injection of alcohol, the application of methyl blue, etc. If the disease has caused deep ulceration before coming under our care and if adjacent lymphatic glands are involved we are often powerless to do more than alleviate symptoms as they arise. Total excision with a plastic operation to replace tissue removed succeeds in a certain proportion of cases. Nevertheless, there are many patients on whom, for some reason we may not practice radical surgery. The one before us is a case in point. The man absolutely refuses to submit to the knife. I propose, accordingly, to pursue a course which has sometimes given me a favorable result and which is always worth a trial in selected cases. This, I think, may be considered appropriate for the experiment. I refer to the topical use of abrus, jequirity or wild liquorice. This substance, if I may judge from recorded literature, is chiefly employed by the oculists in granular lids or trachoma. It is an energetic irritant, the virtue of which seems to depend upon the presence of a special ferment. An infusion or emulsion of jequirity is a most vigorous stimulant to old and sluggish ulcers. From this fact I was led to make use of it in certain cases of epithelioma. Although the ulcer in this case is rather large and deep there is no decided glandular enlargement and it seems possible that it may prove amenable to this method. The application causes excessive inflammation in from ten to forty-eight hours. There is enormous swelling with formation of a hard crust and free suppuration. In the course of a week or less the discharge decreases, the crust loosens or falls, and the exposed surface is seen to be the seat of healthy granulations. In some cases of epithelioma the use of this substance has been followed by complete recovery.

In the hope that so happy a result will occur in the present case I will make the application.

ACNE.

The next two patients exemplify two phases of an exceedingly common disease, especially among young people, and one which is often very unamenable to treatment.

The first case is that of a lad, 19 years of age, upon whose forehead and cheeks are scattered red, isolated papules. A few pustules are also present and comedones abound. The eruption has been in existence for two years. It is limited to the face. The hair is dry, and the scalp is covered with greasy scales. The appetite is deficient and there is constipation. Digestion and assimilation are poor, the integument as a whole irrespective of the actual eruption, has an unhealthy aspect; the pulse is feeble, the heart is weak and irritable.

The disease upon the face is acne, and as comedones and papules predominate it is described as acne papulosa or papular acne. As in addition to the comedones the summit of many of the papules is marked by a blackish spot corresponding to the orifice of the duct, it is also known as acne punctata. Comedones and acne are often found in association or juxtaposition. Both are affections of the sebaceous glands or ducts. It is not strange that, as concerning the same glands, the functional disorder called seborrhea should frequently, as in this case, co-exist with comedo and acne. Their coincident presence points to a profound morbid impression made upon the sebaceous glandular system. The seborrhea here is of the dry variety, seborrhea sicca.

The three disorders to which I have alluded depend upon perversions of nutrition and in many, if not most, instances this malnutrition is of systemic rather than of local origin. In weakly young persons you will often observe the orifices of the follicles dilated and conspicuous. In some instances they are free; in others they are choked by a mass of impure sebum, *i. e.*, comedones have developed. Acne is but an advanced stage of comedo. The plug of sebum creates inflammation of the duct and the gland. The result is acne papules, and these, under the influence of microbes of suppuration, may become transformed into pustules. These pathologic sequences are often reflex. They occur at the age of puberty, they may be caused by genito-urinary disease, by digestive disorders, in diathetic conditions and a depressed or irritable state of the nervous system. They may also be produced by local irritation.

In this case we have no external cause. Unlike a girl of his age he is not tempted to paint or powder his face. He has never been unduly exposed to atmospheric vicissitudes, nor has his occupation been of such a nature as to provoke irritation.

We must, therefore, as in so many diseases of the skin, look beyond that tissue and interrogate other organs. In so doing I have traced the nervous and cardiac debility to the excessive use of cigarettes. He has been addicted for three years or more to the habit of smoking and of late has indulged at every opportunity. There is no doubt that an immoderate use of tobacco has caused in this youth, scarcely more than a boy, an impairment of nerve force, manifested in deficient digestive power, debility of striped and unstriped muscular tissue, anemia, disturbance of general and capillary circulation with, finally, that

morbid state of the sebaceous glandular apparatus for which he seeks relief. It seems rather strange that he should ask medical advice on account of some papules, insignificant in themselves, but magnified in importance by their situation, and apparently ignore far more serious manifestations. I regard this as an interesting example of nicotinism. As a first step in the treatment the patient must totally abandon the use of cigarettes. We shall then aim to strengthen his nervous system and improve his general nutrition. This object can be best accomplished by the use of iron. The stomach, I think, is not too irritable to bear one of the more palatable forms, such as the pyrophosphate. Some of the organic ferruginous preparations lately introduced answer a very good purpose. I will prescribe:

R Ferri pyrophosphatis 5 i 37
 Acidi phosphorici diluti 5 iij 1109
 Elixir. simplicis. 3 j 2957
 Aquæ q. s. ad 3 ij 5914
 M. ft. sol. Sig.—Teaspoonful in water three times a day.

Locally, he shall be directed to bathe the face with hot water night and morning, and after having dried the surface to apply the following lotion:

R Pulveris sodii boratis. 5 iss 582
 Aquæ hamamelidis dest. 5 iij 8871
 Aquæ rosæ 5 iij 8871 M.

Boro-glycerid solution may often be used with advantage instead of the borax. After the above preparation has been used for a week or ten days the borax may be replaced by 0.65 gram of resorcin, which stimulates the parts and aids in restoring them to a normal condition.

The boro-glycerid solution is also useful in dry seborrhea. It is necessary in that affection to clear the scalp of scales and stimulate the local circulation. The oil of ergot is an efficient application, and is often beneficially combined with the boro-glycerid or fluid oleate of mercury. Shampooing the scalp every few days is a serviceable practice. In some cases lotions are more beneficial than ointments or oils.

Another patient troubled by acne is a 17 year old girl, upon whose cheeks, chin and neck are seen a number of pustules intermixed with papules, the former being predominant, and the case being for that reason, properly described as pustular acne. The disease has been in existence for five years. At times the condition is improved and again it is aggravated. The skin is seldom if ever entirely free from lesions. The appetite is said to be good and the bowels regular. The tongue is clean. This is a well developed and physically precocious girl. The case may be viewed as one of those dependent upon the establishment of the menstrual function. Although the eruption antedated by some months the first appearance of catamenial flow, it received a new impetus from that period. In the absence of other cause, therefore, it is reasonable to look for the origin of the disease in the physiologic changes which take place at that time of life. The eruption is generally more abundant at each monthly epoch. When once established the disease may, and often does, persist for several years.

In this case I shall order the face to be sponged every day with hot water, and subsequently the following ointment to be used:

R Resorcini 5 j 39
 Camphoræ gr. x 65
 Unguenti aquæ rosæ
 Unguenti zinci oxidi āā 3ij 78
 M. ft. unguent. Sig.—For external use.

Internally, in order to influence favorably the liver and sebaceous glands, the patient shall have:

R Sulphuris sublimati gr. iij 2
 Potassii bitartratis gr. j 065
 M. ft. capsul. No. j. Mitte tales No. xi.
 Sig.—Three or four capsules to be taken daily.

At the end of four or five weeks the dose of sulphur may be increased to 0.26 or 0.32 grams, and thus continued until an impression is made upon the glands.

ALOPECIA CIRCUMSCRIPTA.

The next patient, a man of 24, has circumscribed patches of baldness upon the occiput and each side of the head. The hair of the beard and eyebrows has also fallen in certain spots. This gives to the whiskers a very shaggy and ragged appearance. There is also partial canities, the hair being whitened here and there in spots. We have searched but failed to find a distinctive parasite. This fact demonstrates that the disease is not a variety of tinea. Ringworm of the scalp usually occurs in children. The denuded patches are generally of a pale red color, though they may be grayish and are covered with fine scales. In tinea tonsurans the appearance of the hairs is characteristic. They do not all fall out and leave a completely bald surface. Some, indeed, are shed completely, but many break off near their points of emergence, giving a peculiar, ragged, stubby or nibbled aspect. The patches in the present case, however, are entirely denuded. The baldness is only in spots, but it is complete. The affected places are white and smooth. There is a total absence of scales. The disease is alopecia circumscripta or areata.

In those places where the beard is involved there is some resemblance to tinea sycosis. I have described the whiskers as ragged, but this appearance results from the irregularity of the hairy covering, and there are no pustules and tubercles denotive of barber's itch. It is necessary to differentiate closely here, but the absence of the trichophyton fungus excludes tinea. The bald patches are of the same nature as those upon the scalp and eyebrows. In extreme cases distinct patches spread and coalesce until the entire scalp and face are deprived of hair. In exceptional instances the axillæ and pubes are attacked.

It is necessary in a given case to distinguish between circumscribed and syphilitic alopecia. The latter, however, is but a single manifestation of a constitutional infection and other concomitant and undoubted evidences of syphilis can always be found. The obligation to eliminate syphilis is very pointed here, as this patient gives a direct history of a wild life, of alcoholic and venereal excess and consequent frequent exposure.

Circumscribed alopecia is of interest as it occurs in children as well as adults, sometimes spreads epidemically in asylums and barracks, occasionally developing with remarkable rapidity; the discussions concerning its etiology are also of interest. It would seem that there is a class of cases dependent upon disturbed innervation, which in its turn may be due to some definite disease of the nervous system, depression from dissipation or emotional causes as shock. To this variety the present case undoubtedly belongs. The man has undermined his nerve force by vicious habits of self-indulgence. The corresponding circumscribed canities is another evidence of nervous exhaustion. In a second well marked class we believe that a parasitic element must be present because of the spread of

the disease from one person to others until a considerable number are involved.

The researches of Sabouraud are important and suggestive in this connection. Others had given much study to the flora of the scalp and the integument, but Sabouraud's conclusions if accepted unite seborrhea, alopecia circumscripta and alopecia as different stages of one malady, dependent upon the activity of the same micro-organism. He regards diffuse alopecia as due to the coalescence of different patches of circumscribed alopecia. There is not time to offer criticisms upon these comprehensive doctrines. I can only question whether the views of Sabouraud serve to explain those cases in which circumscribed alopecia attacks an individual by sudden onslaught.

At all events clinical facts remain stable, and in this patient, debilitated by excess, our aim must be to build up his nervous power and stimulate the peripheral nerves and circulation of the scalp. The first object is attained by enjoining abstinence and continence, by the use of electricity, massage, and such drugs as phosphorus, silver, iron, nux vomica or hoang-nan, camphor, cinchona or kola, etc. This patient shall be given:

R Tincturæ nucis vomicæ ʒ ij ss. 10
 Extract. hydrastis fluid ʒ ss. 16
 Tincturæ gentianæ comp. . . q. s. ad ʒ iv. 128

M. Sig.—Teaspoonful in water three times a day.

Stimulation of the scalp is effected by mercurous oleate, resorcin, naphthol, turpentine, etc.

TINEA VERSICOLOR.

This man, 45 years of age, is annoyed by the presence upon his chest, back and abdomen of yellowish-brown or fawn-colored spots and patches. The eruption has been in existence for about four months. The lesions are slightly elevated and covered with branny scales, which are easily removed.

The appearance is almost pathognomonic. These pigmented, finely scaling spots denote tinea versicolor, or chromophytosis, a parasitic disease caused by the microsporon furfur. Fawn is the usual color, but the hue may vary and in tropical countries may be nearly or quite black. Its general aspect is more like that of chloasma than of any other cutaneous disease. Chloasma, however, is an abnormal concentration of pigment in the mucous layer of the epiderm; tinea versicolor affects the horny layer. The lesions of chloasma are not raised and do not scale; those of chromophytosis are slightly elevated and furfuraceous. Tinea versicolor generally avoids, but chloasma often attacks the face. In vitiligo, or leucoderma, we find a rearrangement of pigment, a transfer of granules from the center to the border of the patch.

The scales of tinea versicolor are easily removed by friction. A mild parasiticide in the form of lotion or ointment usually suffices to destroy the fungus. Boric acid, borax, sulphur, thymol and mercuric nitrate are some of the agents which have been used with success. A reliable remedy is copper oleate diluted with oleic acid or made into a 10 or 20 per cent. ointment. It is antiseptic and parasiticide; moreover, it possesses decided penetrative powers.

The use of water upon the affected parts is to be deprecated. Water feeds the parasite and contributes to the prolongation of the disease.

LECTURES ON TUBERCULOSIS OF THE KIDNEY.

BY CHARLES GREENE CUMSTON, B.M.S., M.D.

Assistant Professor of Surgical Pathology, Faculty of Medicine, Tufts' College, Boston; Fellow of the American Association of Obstetricians and Gynecologists; Corresponding Member of the Association of Genito-Urinary Surgeons of France, of the Pathological Society of Brussels, of the Electrotherapeutic Society of France, etc.

BOSTON, MASS.

(Concluded from page 531.)

LECTURE II.

We will first consider the symptoms to which a tuberculosis of the kidney may give rise. There are two stages to be considered, viz.: The initial stage and the stage of full development, but before discussing these, I will say a few words regarding acute renal tuberculosis, which is not a clinical disease.

It is an accident occurring during the progress of a general infection, and the symptoms of the renal lesion are hidden by those of the lungs, pleura, etc., produced by acute tuberculosis. Two symptoms indicate that the affection has attacked the urinary gland; these are hematuria, be it repeated or simply occurring once, and albuminuria, although this symptom has less importance because it is common in all infectious diseases.

We now come to the symptoms of chronic tuberculosis of the kidney, which are more complete. In the initial stage it may be said that the majority of cases are latent and are consequently overlooked and the progress of the renal lesions is not noticed until the disease is quite advanced, and from a medical tuberculous kidney it has become a surgical one.

The hereditary antecedents occupy here an important place, and the condition of the parents, the bacillosis and genito-urinary antecedents of the patient.

The disease manifests itself by a clear polyuria and frequent micturition, which symptom is the only one present for quite a long time. Clear polyuria, in attacks, is most important. To this symptom we must add hematuria. Smith considers this a symptom of the initial stage, while Guyon compares it to the hemoptysis due to the invasion of tuberculosis in the lungs.

Vigneron found it as the first symptom of the renal trouble and thinks that it would be more often noted if the history of the patient were more carefully inquired into.

Considering now the symptoms of the stage of full development we find that they are more complex, and in order to render them clearer I will divide them into functional and physical. Now the latter may be made out from the appearance of a renal tumor or one developing in the lumbar region, by an edema of the lumbar region, while the functional symptoms are localized, or multiple pains, hematuria, the condition of the urine, the general condition, etc.

Pain, according to Le Dentu, is the most important of symptoms. It may be localized in the kidney or shoot into the neighboring region. Pain has been considered as an initial symptom. In one case reported by Vigneron, the pains had been present for five years, and of six years duration in several cases reported by Palaillon, Tuffier and Bardenbauer; nine years in a case due to Czerny, and twelve in another reported by Monod. But it may be that the pains were produced by small calculi, as in the case published by Burguerolle.

Pain produced by tuberculosis of the kidney is caused by the invasion of the pelvis of the organ and to lesions of the nerves it contains. In many cases, however, pain is completely absent.

The characters of the pains are very varied. Sometimes they occur like a lameness of short duration; sometimes like a feeling of weight in the lumbar region, at others it is acute, very sharp and intermittent; in other patients it will be described as lancinating and continuous.

Generally it occurs in attacks like nephritic colic and radiates from the lumbar to the hypogastric region, thighs and genital organs. Walking, pressure, lying on the side sometimes increase it, at others, produce no influence whatever. All things considered, the shooting pains are frequent and the same in intensity as those localized in the kidney. It only appears at a very advanced stage of the affection, when the tubercles are softened and obstruct the ureter. The radiating pains only last a few seconds generally, but they are so sharp that they cause the patient to cry out. They radiate from above downward, from right to left and left to right, but only exceptionally from below upward.

The pain increases during the periods of retention and stops as soon as the urine, pus and caseous collection passes. When the disease is far advanced, a pain similar to nephritic colic occurs, due to the stopping up of the ureter by masses of broken down tuberculous tissues. The same pain may occur when small blood clots are passed, or it may persist after an abscess of the kidney.

Hematuria.—I have said that in the initial stage of the disease a hematuria could occur. When the affection is fully developed, this symptom becomes important if it presents certain characters besides those of an ordinary hematuria. Those due to tuberculosis of the kidney are spontaneous, intermittent, and of short duration, often only slightly tinting the urine, but the blood is always intimately mixed with the urine. The quantity of blood is sometimes so small as to require a microscopic examination in order to find it. The hematuria of tuberculous kidney occurs without regard to walking or riding and may occur during rest.

The urine.—The characters of the urine are of the utmost importance. In the beginning of the affection it is perfectly clear, but later becomes very purulent and pyuria is generally a constant symptom. The urine is cloudy when passed and remains so. When left in a glass tube a whitish or grayish chalk-like deposit is seen at the bottom; it is sticky and may measure several centimeters in thickness. This large amount of pus is alone enough to indicate the renal nature of the disease. The deposit may also be streaked with blood, the urine above is cloudy and thick. The density is normal and the reaction is acid. There is probably albumin in these urines, although the pus and blood may deceive you in this respect.

Urea usually decreased according to the amount of destruction of the renal parenchyma; sugar is absent, but there is an excess of the phosphates and sometimes of the urates. The phosphates are more particularly ammonio-magnesia.

Microscopically, pus is found as well as leucocytes, fat globules and red blood corpuscles. Deformed and shrunken epithelial cells abound.

Bacteriologically, we find a multitude of bacteria. They abound in the products of excretion and the

urinary system, but as soon as there is a lesion in the latter the bacterium coli is often found. The bacillus of tuberculosis may also be discovered and will then settle the nature of the lesion, although it does not permit us to say which organ is the seat of the disease. The examination for Koch's bacillus should never be omitted and if the first examination should be negative it should be attempted several days in succession until its presence in the urine is demonstrated.

Of all the characters of the urine the most important is the presence of pus. This pyuria presents three characteristics, viz., it is spontaneous, constant and lasting. It may be very abundant and there is a direct relation between this abundance and an increase of the tuberculous lesions. The quantity of pus may be intermittent, sometimes being passed in large quantities, at others in small amount. It is always accompanied by sharp pain, either local or general, anorexia and fever, because the renal pocket contains the infectious material, thus infecting the entire organism, but when the pus passes out with the urine these symptoms subside. When the blood clots contain small grumous particles the size of a pin-head, it is pathognomonic of a tuberculous ulceration of the kidney, according to Vogel, Chopart and Lebert.

I shall now consider the general symptoms as well as those observed in the healthy kidney on the opposite side, the bladder and digestive tract. Guyon has described painful symptoms occurring in the healthy kidney and rectum that he calls reno-renal and recto-renal reflexes and are very curious to study. The healthy kidney without any pathologic change, is the seat of quite sharp pains, similar to those felt in the diseased organ. Generally the ablation of the diseased kidney causes the reflex pain to disappear in the healthy organ.

While the reno-renal reflex is often absent, the reno-vesical is hardly ever wanting and is even an early sign of tuberculous involvement. According to Beal, this reflex is characterized especially by pain in the bladder without any pathologic change in the organ, while Lecorché believes that there is a lesion in the bladder, the pain indicating a tuberculous lesion there. Besides the pain, inflammation of the kidney may produce a frequency of micturition. These three symptoms produced by vesical reflex, frequent, painful and imperious micturition, play an important part according to Beal, Clarke, Roberts and Newman.

This pain is very variable and changing, sometimes only amounting to an abnormal sensitiveness in the hypogastrium. Other patients complain of a very severe pain in the urethra while passing water, which may last after the act, but usually stops when the last drops are expelled. These pains are accompanied by a violent anal tenesmus and even the prostate may become painful.

The micturition besides being painful is frequent, and Tuffier says this condition is sufficient to distinguish tuberculosis of the kidney from a renal neoplasm or a simple pyelo-nephritis. The patient may pass his water seven or eight times in the day and four or six times in the night, sometimes as often as every fifteen minutes or oftener. This frequent and painful micturition is imperious, the patient can not pass his water, but the bladder suddenly contracts and empties itself instantaneously. Incontinence and retention are infrequent in tuberculosis.

For certain English surgeons these reflex symptoms are sufficient to make a diagnosis. Other surgeons believe that they are more than reflex. In Morris' case, who passed water 160 times daily, the autopsy showed a few recent granulations in the bladder. In a case of very painful renal tuberculosis in a woman, with frequent micturition, Tuffier performed a nephrectomy. The patient recovered, but the desire to urinate was in no way lessened by the operation and it was found that there was a commencing tuberculosis of the bladder. Consequently, when there are frequency and pain in urinating in cases of tuberculosis of the kidney, the bladder has also been invaded by the disease and the reflex theory should not be considered.

The coincidence of inflammation of the bladder, especially tuberculous cystitis with tuberculous degeneration of the kidney and ureter, explains, according to Rogers, the reason why we sometimes see cases in which there is an abnormal sensitiveness in the hypogastric region and more or less sharp pain before, during and after the passage of the urine, the emission of which is often repeated and the quantity passed very small, as well as several other symptoms common to all kinds of cystitis. The symptoms given us by the general condition of the patient have nothing characteristic. At the beginning they are not at all marked and a tuberculosis of the kidney may even get entirely lost at this period if properly treated medically.

Infection by retention of the poisonous debris in the kidney and the toxins secreted by the pathogenic bacteria is often added to the tuberculous infection. In this case we have anorexia, vomiting, insomnia, chills alternating with sweating, a dry, red tongue, exaggerated thermometric oscillations; in fact, all the symptoms of pyemia or septicemia. These symptoms are not necessarily present in every case, but when they do exist the indications for action are more clearly defined.

According to Dickenson, a tuberculous kidney rarely gets so large as to form a tumor. On the contrary, Newman thinks that there is soon a slight increase in the size of the organ, but which can not be made out by palpation. Le Dentu believes that in the beginning the kidney is hardly increased in size, but soon acquires a considerable volume. The truth is that the kidney may be increased in size in some cases, while in others the organ is not much larger than normal and consequently can not be palpated. Tuffier had a case of an enormous tuberculous kidney which developed upward toward the diaphragm and was objectively inaccessible. When the kidney is sufficiently large, bimanual palpation and rectal examination will reveal a tumor. By inspection a tumor or swelling will be seen in the lumbar region, sometimes extending to or reaching even above the umbilicus and extending into the iliac fossa. It will also be noticed that this tumor projects under the soft parts from the last ribs to the iliac crest and may be either distended or decreased in size after micturition. Edema from compression is sometimes present. Bimanual palpation must be carefully practiced and will give you a more precise idea of the condition of affairs than will percussion, although the latter should not be omitted in your examination.

You will feel in the lumbar region, sometimes in the anterior abdominal region, a solid, resistant or fluctuating tumor, usually painful on pressure and in

many ways similar to simple pyonephritis. The indurated ureter, which is sometimes deviated, will be felt, like a hard cord, containing bosses and running through the iliac fossa. Rectal examination will complete the physical signs but you must examine the urethra, the prostate, seminal vesicles and bladder in order to ascertain if they contain foci of tuberculosis.

We now come to the diagnosis, and I shall first consider the premonitory stage. For many surgeons, the diagnosis can not be made or it is of extreme difficulty. We must be guided by the etiologic facts of the given case. Slight or vague pains, the initial lameness, must be differentiated from lumbago following a strain or sudden movement, as well as from lumbo-abdominal neuralgia, which may be recognized by its well defined points. But the symptom pain does not signify much until a hematuria appears. When this occurs you must make a differential diagnosis between a hematuria due to tuberculosis of the kidney and that due to hypertrophy of the prostate, acute cystitis, nephrolithiasis and vesical bacilliosis.

Calculus of the bladder.—After a long walk or riding in a carriage or on horseback or bicycle the patient passes blood from the bladder and the hematuria may last all night and in the morning the urine is only slightly colored or may even be clear. If these exercises are again indulged in the hematuria returns.

Hematuria due to vesical calculus has consequently this pathognomonic sign produced by movement and ceases when the patient remains quiet. Under other circumstances, without excessive fatigue, after passing water a sharp pain causes the urethra to violently contract and with the last drops of urine a few drops of blood are expelled, or there may be a jet of blood. There are never any clots indicating a considerable hemorrhage.

Tumors of the bladder.—The hematuria is unique and exists alone as a functional trouble. It is spontaneous, occurring in the morning when the patient awakes after a night's sleep; or in the day, without having worked or exercised the patient may pass a certain amount of blood. The passage of a catheter or washing the bladder causes the passage of blood whether the patient be seated or standing and lasts several days, weeks or even months, the hematuria occurring by attacks usually without cause. The attacks occur at nearer intervals as the disease increases.

The urine is more colored at the end than at the commencement of micturition and much blood is passed. Clots may be expelled or may be arrested in the urethra, producing a serious retention.

Tuberculosis of the bladder.—In the early stage, hematuria is a true hemoptysis, spontaneous and small in amount. It occurs at the end of micturition, disappears without notice, as in tumor of the bladder, but is different from the hematuria occurring in the latter by its very small amount.

Renal calculus.—Hematuria is frequent but not a constant symptom. It is of short duration and small in amount, and does not contain clots. Hematic casts are found in the urine formed by strings of red blood corpuscles and are pathognomonic of a renal origin.

It is characterized by its appearance and increase during walking, efforts and exploration of the kidney as well as during digestion. The attacks are painful, often accompanied by hemorrhages either before during or after.

Contusion of the kidney.—Hematuria immediately

follows a traumatism of the kidney, rarely appearing as late as a week after the accident. What is particularly characteristic of renal hemorrhage is its sudden arrest and reappearing soon again. (Guyon.)

Considering now the diagnosis of a renal tuberculosis in full development, I may say that it makes its presence known by a pyuria following a pyelo-nephritis, by a tumefaction of the kidney and by the symptoms that have already been given.

Pyuria.—A cloudy pyuria is characteristic of a tumor of the kidney. The color of the urine varies from a milky grayish white to green. On the contrary a cystitis shows a purulent deposit at the bottom of the tube with clear urine above after it has been allowed to stand.

Wounds of the kidney.—Superficial wounds do not give vent to hematuria, but if the laceration is deep there is slight hemorrhage.

Pyelo-nephritis.—Hematuria is infrequent, and when it is present is only seen in the form of streaks of blood.

Malignant tumors of the kidney.—Hematuria is absent in almost 25 per cent of cases of cancer of the kidney, in 50 of sarcoma, and in 75 per cent. of renal neoplasms in children.

It is absolutely spontaneous, quiet or movement have no influence in its production. Its appearance is preceded by a sensation of weight, and after the blood has been passed there is relief. The blood is mixed with the urine, which varies in color from red to brown. The mixture is equal and may contain long cylindrical clots and casts of the ureter, which are passed without pain. Pieces of the neoplasm may sometimes be found in these clots. There are attacks of pain which occur at long intervals.

Tuberculosis of the kidney.—I have already described the hematuria occurring in this affection; how when a patient has passed blood from the urethra, and you suspect a lesion of the kidney you must ask yourselves: From what organ does the blood come? What is the nature of the kidney lesion? Which is the diseased kidney?

Now we can localize the hemorrhage from the kidney, although many are the hemorrhages coming from the prostate and bladder. The anterior and posterior urethra can also give rise to a temporary passage of blood at the beginning and end of micturition, but digital examination of the prostate, cystoscopic examination and catheterization of the bladder will eliminate prostatic and vesical lesions.

In vesical tuberculosis as in neoplasms of the kidney, the hemorrhage is spontaneous, intermittent, temporary and small in quantity. The prostate and testicle are usually the seat of tuberculosis when this affection exists in the bladder. In order to differentiate a renal from a vesical tumor hemorrhage you should distend the bladder with an antiseptic solution and wash it out. If after this has been carefully done the last part of the solution withdrawn is deeply tinted with blood you may conclude that it comes from the bladder. The same is the case if the blood appears after forced distention or recto-abdominal palpation.

As a patient passes pus and then this disappears from the urine and is followed by a painful sensation in the lumbar region, nephritic colic and then a sudden reappearance of the pyuria with disappearance of the lumbar pain, you may be sure that the pyuria comes from the kidney. You must also examine the

urine microscopically, and by adding ammonia it will give the urine a gelatinous aspect if it contains pus.

Pyelo-nephritis.—Microscopic examination alone is capable of allowing you to make a diagnosis of tuberculous pyelo-nephritis. Besides the pus you will find single epithelial cells, hyalin casts and cells from the pelvis of the kidney. There are also pieces of renal tissue, phosphates, streptococci, bacterium coli, micrococci and sometimes the bacillus of tuberculosis. The diagnosis is consequently very difficult because it is only a pyelo-nephritis produced by a specific infection.

A simple pyelo-nephritis may become tuberculous, and a gonorrheal cystitis may be the starting point of a tuberculous infection. A dirty catheter may be the cause of a secondary infection on a beginning tuberculosis.

Chronic cystitis.—Polyuria is not marked. The urine after standing separates into two layers, the upper being clear. When during the process of a vesical disease the patient commences to lose strength you should suspect tuberculosis and search for it.

Pus is constantly present during cystitis, and you know the classical experiment with the three glasses which shows that it is above all present at the beginning and end of micturition.

Vesical calculus.—A stone in the bladder creates a particular condition, most favorable for the development of cystitis.

I will now proceed to discuss the diagnosis of a urine containing pus. The principal point is to make a diagnosis of the nature of the infection. Bacteriologic examinations and experimental inoculations are of little value as regards the urine.

You should particularly endeavor to make a differential diagnosis of tuberculous pyelo-nephritis, and pyelo-nephritis produced by a calculus. It is quite easy to make a diagnosis of a pyelo-nephritis produced by a cystitis, prostatitis or stricture of the urethra. Be guided also by the acute progress of the lesion on the disease presented by your patient in order to diagnose a pyelo-nephritis of an infectious disease such as osteo-myelitis, measles, etc.

Your diagnosis consequently is made by three factors, viz.: The general condition, the presence of a tuberculous lesion and absence of an antecedent infection. Hematuria, pyuria being two prominent symptoms of tuberculosis of the kidney. There remains a third, tumor of the kidney, which I shall now discuss.

Tumor resulting from contusion of the kidney.—Sometimes there is a diffuse tumefaction filling the entire lumbar fossa, which is rather hard and adheres to the surrounding parts: this is a peri-renal infiltration. Hemato-nephrosis consists of a distinctly limited, rounded movable tumor with a history of contusion.

Tumor in renal lithiasis.—A history of former lithiasic trouble and pain when the patient moves, will clear up the diagnosis.

Tumor in pyelo-nephritis.—Here we find symptoms of renal neoplasms as projecting abdomen, anterior sonority and renal ballotement. The tumor is round, hard, spontaneously painful or becomes so on pressure, the pain is intermittent.

Tumor in peri-nephritis and peri-nephritic phlegmon.—Palpation always reveals a doughyness, resistance and deep induration localized in the lumbar region. The tumor does not follow the movements of the diaphragm. Peri-nephritis is a lumbar tumefac-

tion, while pyelo-nephritis forms an abdominal tumor.

Hydronephrosis is entirely abdominal and fluctuating, and may be mistaken for an ovarian cyst. It is only by its lumbar situation, and descending and lateral evolution that will lead you to make a diagnosis of hydronephrosis.

Malignant tumors of the kidney.—Tumors of the abdominal wall are immobilized by contraction of the muscles, and their dulness is superficial. Neoplasms of the liver have a sharp border continuing with the liver. Tumors of the spleen have the shape of a cake, the percussion dulness extending upward on the right with a well marked left-sided sonority.

Cancers of the colon cause intestinal obstruction and intestinal hemorrhage, which complications are not met with in tumors of the kidney.

Tumors of the mesentery are median, very movable and extend from above downward.

The clinical diagnosis of tumors of the supra-renal capsule is impossible, while tumors of the ovary and uterus will cause no difficulty in diagnosis.

Consequently when there is renal tumefaction the diagnosis is very difficult. The physical signs are not alone sufficient to indicate the nature of the tumor, and you must take into consideration the functional and general symptoms and age of your patient as well. Do not forget that syphilis of the kidney may produce an enormous tumefaction of the organ, and where this diathesis is suspected try an antisyphilitic treatment before resorting to surgical measures. Examination of the ureter and bladder of the supposed healthy kidney will also contribute to render the diagnosis more precise.

Tuffier reports two exceptional cases of tuberculous kidney. The first presented the symptoms of renal colic. There were no physical signs, pyuria or hematuria, perfect integrity of the pelvis of the kidney and ureter. The attacks were sharp, without lumbar pains. Pains shot down the thighs and spermatic cord; frequent micturition; in fact nothing was wanting excepting the appearance of gravel in the urine.

The kidney was not increased in size and painless. It proved to be a renal tuberculosis with pain, but without retention.

The second case was a woman, aged 42 years, who presented abundant hematuria, no renal tumor, no pyuria. Endoscopic diagnosis showed blood oozing from the ureter. Nephrectomy followed by cure.

When you have a young patient presenting frequent hematuria without any precise renal or vesical symptoms you should suspect tuberculosis of the kidney. If besides, your patient has an early limpid polyuria without any particular marked symptoms in the urinary system, you should be guarded in your diagnosis and prognosis.

In a case reported by Tuffier he found a tumor on the right, but a most careful palpation under chloroform did not reveal the slightest increase in size of the left kidney. Now the left kidney was larger than its mate, but had developed upward toward the diaphragm and was thus concealed.

As a pyelo-nephritis appears without any cause, and nothing can be elicited from the history of your patient, you can as a last resort aspirate the pus from the kidney and make a bacteriologic diagnosis.

The most important point is to distinguish those cases requiring surgical treatment and those that are inoperable. In the female we can easily come to a conclusion by the use of Kelly's and Garceau's instruments.

As to the diagnostic value of the bacillus of tuberculosis, let me warn you that in about 40 per cent. of cases it is not in the urine, while if you resort to experimental inoculation, you will have no result before four or five weeks, and sometimes these are negative.

Now, how shall we make a diagnosis? By observation of former infection which could explain the pyuria, on the general condition of the patient and the presence of another focus of tuberculosis in some other organ.

Which is the diseased organ? Swelling and pain are the two symptoms by which to be guided, but they may deceive you. And in closing let me say that a nephrotomy will allow you to assure yourselves of the character of the urine secreted by the kidney. Sometimes a peri-nephritic abscess will call for incision and you can at the same time ascertain the lesion of the kidney and act as you deem proper.

COCAIN IN OTOTOLOGY AND LARYNGOLOGY.

Presented to the Section on Laryngology and Otology at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, June 1-4, 1897.

BY LEDRU P. SMOCK, AM., M.D.

AURIST AND LARYNGOLOGIST TO ST. AGNES HOSPITAL, PHILADELPHIA.

In 1855 Geadeke isolated a crystalline alkaloid from coca leaves, which he called erythroxylin. Five years later Albert Niemann further investigated this alkaloid and gave it the name cocain.

The power of cocain to produce anesthesia was first called attention to by Fronmueller in 1863, but its practical use became more fully known in 1884 through the investigation and experiments of Freud and Koller.

It was then first used in ophthalmic surgery. Cocain, like all new or rejuvenated remedies, quickly became a panacea "for all earthly woes." While it is still largely used for many external and internal lesions, the aurist, laryngologist and gynecologist probably use it with the greater satisfaction, owing to its anesthetic effect upon the mucous membrane.

Cocain hydrochlorate, when pure, is found in colorless prisms of strong alkaline reaction, giving an astringent, bitter, burning taste followed by a numbness of the mouth and lips.

The following are the tests for the determination of the presence of allied dangerous alkaloids:

Test 1.—Dissolve one-tenth gram cocain hydrochlorate in five cubic centimeters of water (making a 2 per cent. solution) in a clean, glass-stoppered vial, adding three drops diluted sulphuric acid; then add one drop of a 1 per cent. solution potassium permanganate, which produces a pink or violent tint. This tint will not visibly decrease within half an hour if the cocain is free from cinnamyl-cocain and other dangerous impurities.

Contamination with isotropyl-cocain (a violent cardiac poison, which is stable toward the permanganate test) and other basic impurities may be detected by MacLagan's ammonia test, viz:

Test 2.—Dissolve one-tenth gram cocain hydrochlorate in eighty-seven cubic centimeters of water, and then add three drops of ammonia; for a few minutes the solution will remain clear, but a rapid stirring with a glass rod will cause a prompt crystallization.

The most useful solutions I have found are a 2, 4 and 10 per cent. in a saturate solution of boric acid. Where it is desirable to have a longer or an anesthetic

action upon the deeper tissues, the 2 per cent. is the most efficient; as the stronger the solution of cocain the greater the superficial contraction and the less absorption of the drug.

My usual procedure is to spray the parts with a 2 per cent. solution, followed in five minutes by a pledget of cotton, saturated in the same solution; after five minutes apply a 4 or 10 per cent. solution on cotton; in five minutes after the last application the parts will be as thoroughly anesthetized as the idiosyncrasy of the patient will permit.

The use of cocain outside of minor operations, where I believe it will be in most instances superceded by eucain, are many and exceedingly valuable.

The purpose of this paper is to give the personal experience of the writer in the use of cocain on the following acute diseases:

In acute rhinitis, where the nasal mucous membrane is swollen and sensitive, the nasal passages more or less occluded by the intensity of the congestion, the use of a 2 per cent. solution in the form of a spray gives the patient the greatest possible relief and affords the physician an opportunity to cleanse the inflamed membrane.

If the treatment is followed by a 4 per cent. solution spray of antipyrin, then by albolene or blandin in spray form the relief and effect of the treatment will be greatly prolonged, sometimes rendering the nasal passages clear for hours. Many cases will be aborted by two or three such applications at intervals of a few hours.

I have found a pledget of cotton saturated with a 4 per cent. solution of cocain exceedingly efficient in epistaxis, usually no bleeding following the removal of the cotton, which should be left in the nasal passage several hours.

Acute tonsillitis, if treated in its incipency, will frequently be aborted by prompt and persistent use of cocain sprayed or applied to the tonsil and surrounding parts with a brush or cotton covered probe. The only unpleasant effect I have noticed from this treatment is slight nausea, which is promptly relieved by one or two 0.65 to 1.3 gram doses of potassium bromid, and any depressing effects upon the heart's action is rendered unnoticeable by 10 to 15 drop doses of tincture digitalis previously administered.

I have used eucain in similar cases with but fair results; so far in my experience cocain seems much more efficient, causing greater contraction of tissue, while eucain produces greater anesthesia with slight congestion of the mucous membrane as well.

I have frequently used cocain spray in the nasal passages and larynx of patients suffering from an acute attack of laryngeal asthma, the relief being almost instantaneous; also in spasmodic laryngitis, or false croup in children, cocain spray has almost always afforded immediate relief, a second attack rarely recurring, that night at least.

I do not remember a single instance of nausea or depressed heart's action following the use of cocain in either of these affections.

In the treatment of acute otitis, furuncle and acute otitis media suppurations, the most gratifying results have been noticed after the use of a 4 per cent solution.

Saturate a pledget of cotton, warm it over the lamp and gently insert in the canal of the ear and the pain of acute otitis, in many instances, will be quickly and permanently relieved or greatly modified.

Furuncle, if noticed in its incipency, will in most

cases be aborted by keeping the canal of the ear packed loosely with cotton saturated with cocain; if not aborted, it will run a rapid, almost painless course.

In cases of acute suppurating ear with a tendency to hemorrhage, the action of the cocain and boric acid solution is most gratifying to the patient and yields as speedy a cure as any treatment I have used.

In no aural case have I seen or known of unpleasant or toxic effect from the use of cocain, its action probably being purely local with at least but a very slight absorption.

I have, in this paper, avoided the consideration of the use of cocain in operations upon the throat, nose or ear, believing that eucain is a more desirable anesthetic in most cases.

Exception might be taken to this view in the use of the electro-cautery in operations for anterior or middle hypertrophy of the mucous membrane on the turbinate bone; cocain in this case, by more fully contracting the tissue gives a better opportunity for the use of the electric knife.

In the removal of the posterior nasal growths with the Jarvis snare or an electric snare eucain is much more desirable, as the contractile power of cocain frequently renders it impossible to grasp the growth with either instrument.

The abusive use of cocain and the cocain habit, I believe in most cases, follows the use of pills or tablets containing the drug combined with other medicine for the relief of laryngeal and pharyngeal irritation, or taken internally for the relief of some forms of dyspepsia.

I have never seen a case in the medical profession, but am told that many are unfortunately addicted to the habit.

The greatest care should be observed by the physician in all cases where there is necessity for the use of the drug in prescriptions, less the patient, by indiscriminate use, should form a habit more deleterious than either that of alcohol or opium.

I would suggest that all prescriptions be marked: "Not to be renewed without a written order from the physician."

3330 Chestnut Street.

DISCUSSION.

Dr. WILSON—I have never been able to relieve acute otitis media with cocain 4 per cent. I have obtained much more benefit from heat. Does not Dr. Smock think the heated pledget of cotton may have given relief?

Dr. SMOCK—I think the cocain has much effect. Heated applications in otitis are always grateful.

FRACTURES OF THE NASAL BONES.

Presented in the Section on Laryngology and Otology at the Forty-eighth Annual Meeting of the American Medical Association at Philadelphia, Pa., June 1-4, 1897.

BY FREDERICK C. COBB, M.D.

BOSTON, MASS.

Neither in the works on surgery, nor in the special works on the nose and throat is there much information about this subject, and yet any injury deflecting the nasal bones causes a deformity very apparent and disagreeable throughout life, besides often obstructing one of the nostrils. Probably many of these cases occur in childhood, due to falls or blows, and the injury to the nasal bones is so masked by the swelling resulting from the accident that fracture is not diagnosticated. As the swelling disappears, it is noticed that the nose is no longer quite straight, and

that one nostril is somewhat obstructed. These cases often come, in adult life, with a request that the nose may be straightened or the nostril cleared for respiration.

To replace the nasal bones is not as a rule difficult, but to keep them in place has been found to be almost impossible. After fracture, splints have usually been applied to the inside and must be worn two or three weeks. Although the lower meatus is very tolerant of tubes or splints, as shown by their use in the correction of septal deviation, the middle meatus and the upper portion of the nasal cavity is not so accommodating. Pain, sneezing and swelling of the conjunctiva on the affected side usually follow the introduction of splints high up in the nose, and the patient is unable to bear the treatment. Therefore, after correcting the nasal deformity as well as possible at the time by etherizing, and straightening the nose, the surgeon is usually obliged to content himself with the hope that the nasal bones will remain as he has left them, a hope which is frequently disappointed. It may be asked, what is there to deflect the nasal bones after they have been placed in proper position, and I believe the answer can be found, first, in the spring-like elasticity of the cartilaginous septum which is often thrown out of its normal conditions by

whether as the result or cause of the misplaced nasal bones is a more doubtful question. My view is that the blow which fractures the nasal bones also dislocates the septum more or less from its bony attachment, thus altering its normal direction of spring and prevents its exerting that pressure to keep the nasal bones in their mal-position. In one of the cases I cite, the septum could be seen, on pressing on the bridge of the nose, to alter its position from a deflection partially obstructing one nostril, to one giving almost perfect symmetry to both nostrils; yet when the nasal bones were released the septum returned to its old position. This case illustrates the fact that the replacing of the nasal bones without splints can not always be trusted to keep them in position. For some time we have made attempts to keep a pressure on the bridge of the nose by the use of the band of a head mirror, but it was found that no matter how tightly the strap was pulled, the looseness of the scalp allowed so much movement of the apparatus that it

Figure 1.

the accident; and secondly, in the fact that an organ so exposed as the nose can not be well protected against slight pressure, during sleep especially. When a very slight impulse will alter the position of a fractured nasal bone, we can not wonder that they so rarely stay in place. The elasticity of the septum, if its normal attachments were unaltered, would tend to keep them in their position after the nasal bones had been restored to their normal position. I believe many, if not most, fractures of the nasal bones alter the usual attachments of the septum to its neighbors, and the co-existence of dislocation of the cartilage from its attachment to the maxillary process and the superior maxilla is often found with a long standing deviation of the nasal bones. Other septal deformities, also, are usually present in such cases, but

Figure 2.

was practically inefficient in holding the nasal bones in place. Noting the difficulty of turning one's hat on one's head suggested the idea of having a band made of steel shaped to the head by some similar method. This plan has seemed to do so well that I suggest it for your consideration. The band is shaped to the head by the use of the hatter's form, by which the shape of the head is accurately marked on a sheet of paper; but this method required an enlargement of the paper model and more complicated apparatus than was necessary. It was found also that as it corresponded to the head in only one plane, the steel band being wider than that plane could not be so well shaped to fit the head. For patients accessible to an instrument-maker, a strip of lead was used, fitted to the head at the level desired, and then a steel ring

was made to correspond with it. For physicians living at a distance from an instrument-maker, the following plan is suggested: A strip of oiled silk is wrapped about the patient's head at the level desired for the band, and a few turns of a roller bandage of plaster of Paris being moistened, are applied around it, and allowed to harden in position. When the plaster is removed, a cast of the inside may be made by oiling it and filling it with plaster, or the hardened bandage may be sent direct to the instrument-maker, who can shape a steel band to correspond with it. The head-band is prevented from sliding downward by a strap passing over the head, and from sliding upward by a chin-strap. It should be broad enough to allow very little lateral twist, but the effect of such twisting can be neutralized by the screw attachment as well as by the spring. The nose being unbandaged, its position can be clearly seen by the patient, and the pressure of the spring on the nasal bones may be increased or diminished as may be necessary. If there is a depression as well as a lateral motion of the nasal bones the depressed fragment should be first pried up into position from the inside of the nose, under ether, and then packing applied high up in the nostril, if possi-

ted to the left, while the nasal bones inclined to the right. On examination of the nostrils the septum was found to be deviated anteriorly into the right nostril at about the junction of the bony and cartilaginous septum. On pressing the nasal bones to the left, the septum straightened itself, but not completely. The nasal bones were movable, the fracture appearing to be at their junction with the frontal and superior maxillary articulation. The fracture was compound, for bleeding occurred from the right nostril on moving the bridge of the nose laterally. The nasal bone on the left side was depressed from an old fracture, dating back several years. The splint, as shown in Fig. 2, was applied, and at the same time the depressed nasal bone was pushed into place from the inside and held there by a pledget of antiseptic wool. This had, however, to be removed within ten days on account of pain and discomfort, as the patient was unable to bear it. The splint caused no discomfort, and the septum and nasal bones under its pressure returned to their normal position. The splint was kept on twenty-five days, and the nasal bones were found to be firmly fixed in position. The only inconvenience resulting from the splint was a slight reddening of the skin at the point of pressure of the pad. Figs. 1 and 3 show condition of nose before and after treatment.

Figure 3.

ble. The discomfort and conjunctivitis resulting are the main objections to this plan, but there seems to be no other way if the fracture be a depressed one. If the pressure of the pad against the nasal bones produces any irritation of the skin, the pad may be moved slightly higher or lower without altering its efficiency. I have seen no inconvenience except a slight reddening of the skin follow the use of this splint. The following cases and cuts illustrate the use of the splint:

Case 1.—J. L. K., age 25, entered the Massachusetts General Hospital, February 8, with the following history: Three days before, he was assaulted by a man with a club, and received several violent blows on the bridge of the nose. Examination showed ecchymosis of the upper left eyelid and under both eyes. The nasal bones were deviated to the right side, and the bridge of the nose was easily movable. The left nasal bone was somewhat depressed; the tip of the nose was deflec-

Figure 4.

Case 2.—H. C., a girl, aged 8, entered the hospital with the following history: She was accidentally struck on the right side of the bridge of the nose by a base-ball bat. The physician in attendance writes me that the nose was so much deviated that a probe was with difficulty introduced into the left nostril. He, however, replaced the nasal bones as well as possible, and she entered the hospital for further treatment. Examination showed a marked deviation of the nasal bones to the left. On gently pushing the bridge of the nose it was found to yield easily, while on rhinoscopic examination, the septum was seen to alter its position from a considerable deviation to a nearly vertical position. The nasal bones were dislocated from the nasal process of the superior maxilla, and were movable upon each other. The splint was applied, as shown in Fig. 4, and kept on two weeks, leaving a nose apparently perfectly straight externally, and showing internally a nearly vertical septum without any obstruction of either nostril. No discomfort resulted from the splint, nor were there any marks of pressure on the skin except a very slight reddening.

11 Marlborough st.

DISCUSSION.

Dr. ROE—The apparatus devised by Dr. Cobb for the treatment of fracture of the nasal bones is an ingenious one, but he has evidently made it without previous knowledge of a similar instrument that was devised several years ago by Adams of London, called Adams' nasal truss, which is figured in Watson on "Diseases of the Nose." Longitudinal fractures of the bones of the nose, as a rule, require little or no retentive apparatus, for the bones almost always remain in place after the fracture is reduced; but transverse fractures of the nasal bones will not remain in place and therefore require retentive apparatus. In these cases I use both an external and internal support. I fit a metallic shield, usually made of aluminum on account of its lightness, cut and bent so as to conform to the size and shape of the nose before the injury. This is placed on the outside of the nose and held there by adhesive plaster. For the inside support, after the bones are replaced, I pack the vault of the nostril lightly with antiseptic gauze. Below this I insert a spring made of light brass spring wire, nickel plated. One arm of the spring passes up under the dressing, while the other rests on the nose. To guard against irritating the tissues, the arms of the spring are covered with rubber tubing. The tension of the spring can be so regulated as to give the exact pressure required. The pressure in these cases should always be light, for the reason that very little is re-

quired to retain the bones in place, there being no muscular action to displace them. Moreover, if there is undue pressure the dressing at once becomes irritating and unbearable. In some cases Adams' truss or Dr. Cobb's apparatus might be of special service, but I have found no cases in which the plan I have described has not given most excellent results.

Dr. STRUCKY—I have tried Dr. Roe's method and I find that the cotton or gauze produces considerable irritation. I now use a modification of Asch's tube, and get very good support. I tried sheet lead outside, but found it heavy, and now use dental rubber. I bend it and hold it with rubber adhesive strips. I put the Asch tube in hot water until it becomes pliable and then apply it.

Codman & Shurtleff,
Boston.

The CHAIRMAN—I have used satisfactorily a plaster of Paris dressing. It is not always possible to get a splint such as has been described, and in two cases I have had difficulty in keeping splints from slipping. I have the patient lie down and adjust a plaster of Paris mask. This is made quite thick over the nose and in the angles between the nose and cheek; curvatures in the upper contour are left for the orbits, and it then spreads out over the cheeks to the ears. It should be lined with thin rubber cloth. The fragments should be previously adjusted and maintained in the right place by pressure during the "setting" of the plaster. Tie the mask by a couple of tapes, one over and one under the ear, coming together behind the head. The results have been very good. If you wish to get additional pressure, take a bit of cotton and put it within

the mask where pressure is desired, when you dress the case, every day or two, adding cotton as you require pressure. An intra-nasal tube or splint is sometimes necessary in addition. The only objection to this method is the temporary disfigurement.

Dr. ROE—I have never found any bad results from internal support if there is not too much pressure. Pack with cotton lightly, not too firmly.

Dr. COBB—We have tried the plaster mask in the Massachusetts Hospital and it did not seem strong enough. Masks of metal, though they kept the relative position of the nasal bones, did not keep the whole bridge from deviating one way or the other. Possibly a combination of splint and bandage might do well.

CERTAIN CONDITIONS OF THE TONSILS WHICH LIMIT THE USEFULNESS OF THE TONSILLOTOME.

Presented to the Section of Laryngology and Otology, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY ARTHUR AMES BLISS, A.M., M.D.

Laryngologist and Aurist to the German Hospital, Philadelphia, and to the Pennsylvania Institution for the Deaf and Dumb.

Fellow of the American Laryngological Association, and of the College of Physicians of Philadelphia.

PHILADELPHIA, PA.

It seems a safe assertion to say that the tonsillotome is the instrument most frequently selected by the surgeon in the performance of tonsillotomy. In most instances, however, I think that excision would be more effectually done by other means than by the guillotine-knife.

This opinion may appear easier of acceptance or denial, if we think for a moment why we should excise a tonsil at all. The operation is done either for the removal of a mass from the fauces which occludes the respiratory tract and interferes with phonation, or for the purpose of freeing the throat from the presence of tissue already so abnormal that it readily becomes infected by any micro-organisms which produce an inflammatory process. In either event, unless the work of excision is done thoroughly, the end sought is not attained, and the instrument depended upon has failed in its work. Why should the tonsillotome be an instrument peculiarly well adapted by its size, shape and action to fail in its work? This question may be answered by considering the conditions usually presented by the class of tonsils where the operation of excision is justifiable.

The text-books of anatomy tell us that the tonsils are almond-shaped masses of lymphoid tissue placed within the somewhat triangular-shaped space between the palato-glossus and the palato-pharyngeus muscles; that they are about one-third of an inch wide by three-fourths of an inch long, the vertical being the longer diameter. There are many such tonsils, yet, even within normal limits, there are such enormous variations from this standard that such divergences can not always be considered evidence of disease. The tonsils lie at a point where in embryonic life a very complex development is in progress. Between that anterior end of the fetal fore-gut which pushes itself upward beneath the hind-brain, and the invagination of the epiblast which forms the stomodeum, lies the "primitive velum," separating the fore-gut from the anterior region of the future mouth. This hypoplastic membrane will soon disappear, and the mouth will be formed part from the hypoblastic element of the fore-gut, part from the epiblastic element of the stomodeum. Both of these elements enter into

the formation of the tonsils; while, in the meantime, nose and mouth are as yet unseparated, and all the possibilities of arrested or asymmetric development lie in the immediate future. In other words, in no part of the body are variations in growth, arrest or unsymmetric development more common than in this naso-facial region. This complexity of development may account for that great variation in the tonsils which render them an exceedingly difficult structure to classify under a distinct standard of normality.

I think that within a strictly normal condition the upper extremities of the tonsils should appear, when the mouth is opened and the tongue slightly depressed, about on a level with the dorsum of the tongue at the plane of the fauces. The posterior faucial pillars above this point should not be concealed by an extension upward of the tonsils, nor should the latter be prominent at the sides of the base of the tongue. The free surface of the tonsils should not project into the faucial space beyond, or but very slightly beyond, the level of the free margins of the anterior and posterior faucial pillars, nor should these pillars be attached to the tonsils of their respective sides.

I think that this rather negative description of the tonsils will include that great variety of shapes and sizes which these lymphoid masses assume, even within limits that are not essentially pathologic. I believe, too, that a tonsil which transgresses my rather broad limits will do one of two things—possibly both. It will narrow the caliber of the oro-pharynx, thus interfering with proper respiration and deglutition, or it will press upon the base of the tongue or upon the velum palati, so as to interfere with the proper movements of these parts in phonation.

Two varieties of tonsils will do these things, the simple overgrowth, or simple hypertrophy, and the tonsil enlarged as the result of inflammatory processes, either now quiescent or still active. The tonsil simply overgrown stands out clearly defined from the sides of the fauces; is soft in consistence; is free from adhesion to surrounding parts, and is covered by the pale pink mucous membrane of the mouth.

The second variety of enlarged tonsil, however, presents most varied degrees of distortion. It is generally crossed by a wide band of connective tissue, commonly sweeping backward and downward from the anterior faucial pillar. Instead of such a simply formed capsule, the covering membrane may assume the form of bands lacing in different directions, like the meshes of a net or the intercellular walls of a honeycomb. In either variety the capsule renders the tonsil a hard, rubber-like mass, adherent to the anterior pillars, and often concealing the posterior pillars—to which it may also be attached—and extending upward almost to the base of the uvula. Such a tonsil may be smooth on its free surface, if the tissue has not been subject to frequent attacks of inflammation which have resulted in the formation of abscesses. It is apt to lie, much as the eye does between its lids, the capsule simulating the latter and producing a large, firm, smooth, rounded mass, whose margins are not sharply defined, but lose themselves in the surrounding tissues of the velum, faucial pillars and pharyngeal wall. If abscesses have occurred, the smooth surface will be broken by masses of irregular ragged projecting tissue, separated from one another perhaps by deep recessions or pockets, in many of which lie large masses of cholesteatomatous material.

There is still another form of tonsil which requires

excision, an especially vicious variety. I refer to the hard nodular sclerosed tonsil, diffused irregularly over the space between the faucial pillars, usually adherent to them, and yet appearing to be small in size. Such a tonsil is almost entirely enveloped by a fibrous capsule, extending usually from the anterior pillar and enshrouding the free surface of the lymphoid tissue. By contraction of the capsule, perhaps, or from some other cause, the tonsil appears to be rotated backward, so that its free lateral surface presents backward and inward toward the posterior wall of the pharynx. By means of a blunt hook passed around its posterior margin, such a tonsil can usually be drawn forward, so that traces of an exposed lymphoid surface can be seen. This variety of tonsil readily takes on an inflammatory process, and even when not flaming out in vicious attacks of tonsillitis, is apt to maintain a condition of irritation or even inflammation in the pharynx and larynx.

Now the tonsillotome can excise only such masses of tissue as will engage within the ring-frame of its guillotine-knife. It can be of no service whatever for the sclerosed and contracted tonsil. It can not grasp the large diffuse encapsulated tonsil, because its frame can not embrace such a growth, whose bulk is not clearly defined, but which merges into the surrounding tissues, while its free surface is covered by a smooth hard slippery capsule. By firm pressure against the free surface of such a mass, a small amount of tissue may be squeezed through the frame of the tonsillotome, and when this shaving is gashed off the instrument has performed all that it can do.

In the case of the large simple hypertrophy, there is a limited field of usefulness for this instrument. The caliber of the ring-knife's frame varies from three-quarters of an inch to one inch in its long diameter; its width is seldom more than three-quarters of an inch. Its long diameter is usually parallel with the shank of the instrument, while, as shown long ago by Dr. Carl Seiler and others, it should always be set at a right angle to the shank, thus corresponding with the position at which the tonsils lie in the fauces. Even when so set, however, it will serve only for instances where the enlarged tonsils do not exceed the limits of its ring, while in not a few instances we see these simple hypertrophies so large as to extend from the base of the uvula almost to the free upper margin of the epiglottis. Yet in those cases in which the tonsillotome will surround and excise the bulk of the growth, it fails to remove those portions of the mass which very often are most productive of irritation. I mean the extreme lateral portions, in cases where the tonsil has so filled the tonsillar space as to press upward against the velum palati and outward against the faucial pillars. The free projecting mass may have been removed, but these offending portions remain, still causing pressure and irritation and ready to become inflamed. Now, I believe that an operation even so comparatively simple as tonsillotomy had better not be attempted unless it is performed thoroughly and effectively. It seems apparent that the tonsillotome—that most generally used agent for excision—can be relied upon to do effective work only in that very limited proportion of cases which I have indicated. I can not but think that its imperfect work has done much to bring a certain discredit upon the operation of tonsil excision and may account for the not infrequent reports among the laity that the tonsils

have "grown again" after an excision has been performed.

In place of the tonsillotome I prefer an instrument which permits of a dissection of the parts to be removed from the surrounding tissues, a method of precision which does not leave the amount to be removed to the chance of engagement or non-engagement of the ring-knife. This result is attained by the use of a small firm crocodile forceps (Farnham's forceps) held in one hand and by means of which masses of the tonsil tissue are grasped. The parts thus held are excised by means of stout-bladed scissors whose handles are set at an angle from the blades so that the field of operation is not hidden by the operator's hands. The bulk of the tonsil mass is quickly cut away, and then the parts lying between the faucial pillars are carefully drawn out and excised. In adults this work can be done under cocaine. In children it is more frequently necessary to employ general anesthesia by ether, and use a mouth-gag. This is held by an assistant, who also holds the patient in a sitting position, thus permitting the blood to escape freely from the mouth. As in children hypertrophied tonsils are so commonly associated with hypertrophied adenoid tissue in the naso-pharynx, this method enables us also to combine the operation for the removal of this latter mass and the tonsillotomy under the one etherization. Dr. John Farlow of Boston, has devised a powerful cutting forceps for the tonsils, which he calls the "tonsil punch." It is a useful instrument in cases where the size of the patient's mouth permits of its employment. I have not found it of use in the mouths of children, owing to its large size. The operative procedures briefly indicated can be modified by the use of a great variety of instruments. Reference is simply made to this general method of operation as being in the great majority of cases vastly more effective than the action of the tonsillotome.

THE TREATMENT OF CHRONIC INFLAMMATION OF THE TONSILS.

Presented to the Section on Laryngology and Otology, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY J. A. ELLEGOOD, M.D.
WILMINGTON, DEL.

The brevity of this paper will preclude the consideration of inflammation of the tonsils due to syphilis, tuberculosis, lupus and malignant disease. Chronic amygdalitis is primarily and essentially a chronic disease of the tonsillar crypts, and rational treatment must aim at their destruction or removal. While usually attended with hypertrophy, such is not always the case. The enlargement is often so slight as to be hardly appreciable, and the morbid process is of so low a grade as to present, except at occasional intervals, but few of the usual features of inflammation. Knight has divided hypertrophied tonsils into three groups: 1, those that are decidedly increased in volume and constantly project beyond the palatine arches; 2, flat diffuse tonsils which project but slightly into the fauces except during the act of retching; 3, those that encroach upon the pharyngeal space and yet do not appear beyond the free margin of the half-arches, for the reason that in consequence of repeated attacks of inflammation the interior pillar has become firmly adherent. In process of enlargement the tonsil carries with it

the palato-glossal fold, which may be much thicker than normal or may be spread out over the surface of the tonsil in a thin veil of mucous membrane. In chronic inflammation much of the stroma may have degenerated into cicatricial tissue enclosing some infected crypts which may be partially or entirely closed. Such tonsils, although presenting an atrophic appearance, are in a state of chronic inflammation. The development of cicatricial tissue is usually the result of repeated acute attacks. Hypertrophied tonsils may be hard or fibrous, and soft or adenoid. As a rule, the older the patient and the longer the disease has existed the more dense, fibrous and highly organized the tissue; whereas the younger the patient and the more recent the hypertrophy the softer and more spongy the tonsil. While tonsillar hypertrophy tends to disappear with puberty, its ill effects upon the general health and permanent injury to neighboring organs before that age is attained may be very marked and are well known. The marked improvement which almost invariably follows its removal is a striking confirmation of its harmfulness. The treatment of chronic tonsillitis must be adapted to the age and general condition of the patient and to the condition of the inflamed tissue. The removal or destruction of the diseased follicles being indicated we have to consider the best means of accomplishing this end. But little can, at best, be expected of constitutional treatment, since whatever constitutional defects or weaknesses that are associated with chronic inflammation of these organs are rather the result than the cause of the tonsillar trouble. Local applications of iodine and astringents brushed over the surface of the tonsil for the purpose of causing their resorption are of questionable utility. Of still less use is the absurd practice of application of iodine or its compounds to the skin over the region of the tonsils. We will first consider the treatment of that class of chronic tonsillitis characterized by decided increase in volume and encroachment upon the faucial space. This form of hypertrophy is most frequently found in young children and is spongy in consistence. The surface of the tonsil is usually comparatively smooth and the growth more or less pedunculated. In some cases, however, the surface is irregular or lobulated, the irregularity being usually the result of repeated acute attacks of inflammation or to distended crypts. The best and most expeditious method of treating the majority of such cases is by excision with the guillotine. The choice of instrument must be left to the individual operator. The operator must select his cases in using the knife. He must assure himself that there is no tendency to hemophilia. The operation should not be done on acutely inflamed tonsils, for a lacunar tonsillitis is often diphtheritic. Neither should it be done during a general febrile condition of the patient nor during an epidemic of croup or diphtheria. It should be done with extreme caution on patients past the age of puberty. Every facility should be at hand in all cases for arresting hemorrhage. The tonsils of patients who have arrived at the age of puberty are likely to be more fibrous and it is in such cases that excessive bleeding is liable to occur. In fact, at that age, unless such growths are decidedly soft or pedunculated, the knife should be used with great caution. The best time for operating is in the morning, as it is well to have as long a time as possible to elapse before the patient assumes the recumbent posture. The use of general anesthesia is

seldom necessary. The operation is not a very painful one and a little tact will, in most cases, obviate the necessity of general anesthesia. Any child that will quietly submit to etherization will as quietly submit to tonsillotomy, for the distress of the former exceeds the pain of the latter. When force becomes necessary to overcome the objections of the patient the shock of an anesthetic is no less than when the operation is performed without it. Besides requiring more time general anesthesia adds its own danger and increases the tendency to hemorrhage. When used, the choice of an anesthetic must be left to the operator. The writer prefers nitrous oxid. In using the guillotine without general anesthesia, on tractable patients with fairly large tonsils, a weak (2 to 4 per cent.) solution of cocain may be brushed about the base of the tonsil a few seconds before the operation is performed. In intractable patients its use may be well dispensed with. A strong solution or the prolonged use of cocain increases the tendency to hemorrhage. As much of the tonsil should be removed as projects beyond the half-arches. It is true that in many instances the removal of a thin slice from the surface will be followed by atrophy. This is explained by the fact that the constricted orifices of many of the diseased and distended crypts are removed, giving an opportunity for free drainage. Hemorrhage usually ceases spontaneously in a few minutes. When moderately excessive, cold water, ice and the gallo-tannic acid mixture will usually succeed in arresting it. The prejudice that exists against the use of the knife is not confined to the laity and the specialist will frequently be confronted by the necessity of resorting to other means of reducing the hypertrophy. Next to the knife the galvano-cautery is unquestionably the best agent. Its application is painful, even when cocain is used within the limit of safety. Few small children can be induced to submit quietly to its use. Before being used the lacunæ should be carefully sought and cleansed, and in some cases curetted. To sear the orifice of a dilated crypt filled with infectious material is but to intensify the condition it is intended to remove. A cherry red electrode should be well introduced into the crypt and retained for a few seconds. It should be made to burn its way out through the constricted orifice. As only a few crypts can be treated at one sitting, several treatments at intervals of from one to two weeks will usually be required. The reaction is usually not very great. Thorough curetting and cleansing of the crypts, followed by the application of tincture of iodine, or a bead of nitrate of silver or chromic acid fused on a probe, will in most instances be followed by good results. This treatment though protracted has the advantage of practicability. Few parents or patients will object to it. Cocain can be used and the operation made painless. The cocain solution should be carried well into the crypts by means of a cotton wrapped probe. More prompt results can be had if after cleansing and curetting, the tonsil knives devised by Dr. Leland of Boston are used. The olive-shaped tip of the knife is introduced into a crypt in the upper part of the tonsil and then turned downward and inward and made to come out by another in the lower part. The substance of the organ between these two holes is then cut through. This can be repeated from three to ten times at a sitting, until the surface of the tonsil presents the appearance of being full of slits. There is usually not much bleeding and this knife can oftentimes be

introduced to its fullest extent without danger. Nitrate of silver, chromic acid, trichloroacetic acid or tincture of iodine may be applied to the slits as well as to the crypts. This treatment will be followed by a satisfactory result in those cases in which from lack of consent or contraindication against the use of the knife, cleansing and applications of caustics alone can be used. Myles nasal curettes with malleable shanks are very satisfactory for curetting the crypts. The writer has not had satisfactory results from the application of hydrochloric acid as suggested by Kendall. The cold wire snare causes great pain. The galvano-cautery snare is sometimes useful in fibrous tonsillitis. In many instances the guillotine can be successfully used on the flat diffused tonsils by having an assistant press over the region of the tonsils, causing them to project into the pharynx. Only a small or thin portion may be removed, but the thin slice will contain the constricted orifices of several crypts. Many of the methods suggested for the treatment of the first group of hypertrophies will be applicable in the treatment of the second and third. The writer has obtained most satisfactory results from galvano-puncture in flat diffuse tonsils. If after the destruction of as many crypts as can be found there still remains a considerable portion of hypertrophied tissue, its reduction can be speedily accomplished by puncturing the stroma with a galvano-cautery wire. About half a dozen punctures distributed at about equal distances and extending to a depth of from one-fourth to one-third of an inch should be made at a sitting, and repeated in from ten days to two weeks. Dr. Arthur A. Bliss has devised a pair of scissors for the removal of this class of hypertrophies. Leland's curved tonsil knives are especially adapted to separating the adhesions of the tonsil from the anterior pillars of the fauces, after which it is usually possible to remove the hypertrophy by means of the guillotine. A great variety of reflex phenomena results in adults from chronic inflammation of the lacunæ. There may be little or no appreciable hypertrophy of the tonsillar tissue and the disease may be limited to a few crypts. These will often require careful search and be found, as a rule, at the upper part of the tonsil, the orifices being hidden behind the palatine folds. These diseased crypts contain decomposing cheesy material made up largely of leptothrix elements. They may contain chalky material. They should be emptied, cleansed, curetted and slit down to the lowest part. The thorough use of the galvano-cautery point will make the cure more certain. Fibroid degeneration of the stroma probably causes little trouble other than constricting the orifices of the crypts and preventing the escape of their contents. Chronic abscess, though undoubtedly having its origin in infectious material that has gained entrance through the crypts, is largely confined to the peri-tonsillar tissue. As much of the abscess wall should be removed as possible, the surface thoroughly cleansed and curetted, and brushed with pure carbolic acid.

Equitable Building.

Gelatin as a Hemostatic.—Carnot states that a solution of gelatin with a little sodium chlorid applied locally acts promptly as a hemostatic, healing by first intention being favored. The solution employed contained 5 per cent. of sodium chlorid. It was sterilized before use and brought to the temperature of the body at the time of application. — *La Presse Médicale*.

PERITONSILLITIS—ITS ETIOLOGY AND TREATMENT.

Presented to the Section on Laryngology and Otology at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY KATE W. BALDWIN, M.D.

PHILADELPHIA, PA.

Peritonsillitis, quinsy, phlegmonous pharyngitis, pharyngitis abscedens, peritonsillar abscess, parenchymatous tonsillitis and the other names under which this condition is described matter little, but to find the cause and relief of this frequent and most painful throat affection is of immense importance to those suffering from it. Schech classes it, next to tuberculosis, the most painful.

It is without doubt of bacterial origin. Cold, rheumatism, gout, trauma, in fact anything which lessens the resistance of the tissues, may predispose to, but not act as the exciting cause. Rheumatism, cold, trauma, etc., do not go on to suppuration unless accompanied by some member of the great family of bacteria; here we probably have a streptococcus. The tissues involved have been by many writers very loosely considered. Some state that the glandular tissue is primarily involved, the inflammation extending to the surrounding tissue. It is even described as parenchymatous tonsillitis. Others claim that it commences in the surrounding tissue and that the tonsil is only secondarily, if at all, involved. It may, and not infrequently does, follow an acute lacunar tonsillitis; however, quinsy proper is a peritonsillitis and should not be confounded with tonsillitis, a much less painful and less dangerous condition.

The locality is called by Chiari the spatium pharyngo-maxillare; and is bounded by the tonsil, the internal pterygoid muscle and the palatine arches. The swelling may extend into the post-nasal space, causing complete obstruction between the nose and throat and may also descend toward the larynx producing edema of the latter and threatening dyspnea.

Untreated the disease usually goes on to suppuration, every day adding to the pain and all other symptoms, until the pus is evacuated, which usually occurs within fourteen days, through the anterior palatine arch, but may be through the posterior palatine arch or below the tonsil. The pus may burrow into the cellular tissue of the throat, into the esophagus, into the mediastinum, the submaxillary gland or the muscles of the tongue. There may be erosion of the carotid artery, or general septicemia may follow. In one case recorded as quinsy, there were repeated hemorrhages, causing the death of a patient. Even in untreated cases the prognosis is good, exceptional cases however occur. Much suffering may be avoided by painstaking and thorough treatment, and it is to this that I wish to call special attention.

Many remedies have been suggested for the treatment of this painful affection, but from none have I seen the good results that come from the use of the spirits of turpentine. I do not find it mentioned in the books, but claim no originality in its use for the treatment of quinsy, it having been suggested to me by Dr. ———, who some five years ago was doing special work at the Philadelphia Polyclinic, he having learned of it through a German physician. There being an abundance of material at the Polyclinic, Dr. Freeman was quite glad to have me test its efficacy, and kindly turned over to me all the cases that presented.

For several years I have treated all cases coming under my observation, both private and dispensary, in the following manner. Thorough cleansing of the throat and nose with a mild alkaline solution, followed by the application of the spirit of turpentine, equal parts with the compound spirit of lavender, disguising the taste of the turpentine by the addition of a few drops of the oil of anise or gaultheria. In some cases I use the turpentine full strength. This is applied to all the inflamed tissue, as thoroughly as possible, with cotton on a fine applicator, behind the soft palate, into the crypts of the tonsil and where possible between the tonsil and the pillars of the fauces. For use between visits, I order the patient to apply the above mixture every one to three hours. A mercurial followed by a saline laxative is usually indicated—in the rheumatic or gouty subject appropriate constitutional treatment must be instituted. In other cases I use codein to control the pain. As much nourishment as can be taken, either hot or cold as most comforting to the patient. If seen early, this treatment will abort an attack; later, will prevent the formation of pus and the involvement of the opposite side. It will, in nearly all cases prevent involvement of the opposite side even though pus be already present on the one affected. From a number of physicians, using this plan of treatment, I have had most favorable reports, one reporting equally good results from its use in tonsillitis.

Without detailing special cases I will say that all I have thus treated testify in favor of this over all other methods of treatment, many of these patients having had repeated attacks and treatment by many different methods. After the turpentine treatment some have never had a second attack, others, who were accustomed to attacks of peritonsillitis every two, three or four months have gone two or three years without any recurrence. In advanced cases where the mouth can be but slightly opened, it will require skill in the use of light and instruments to thoroughly treat a case. After the acute attack has subsided the throat and nose should be put in as good condition as possible, great care being taken to remove all adhesions between the tonsil and the surrounding tissue. Instruct the patient to report at once upon recurrence of symptoms pointing to another attack.

As a germicide Koch reports: "Oil of turpentine destroys anthrax spores in five days but failed to do so in one day. The development of anthrax spores is prevented by 1-75,000."

Rudling states that the addition of 1-200 to nutrient gelatin prevents the development of bacteria.

I have said nothing of symptoms, they being so characteristic that once recognized can scarcely be mistaken. The position of the head, and the peculiar contortions of the face with every attempt at swallowing, with more or less fixation of the jaw, is quite sufficient for a diagnosis, in the majority of cases, without even inspecting the throat.

DISCUSSION ON PAPERS OF DRS. BLISS, ELLEGOOD AND BALDWIN.

Dr. SEISS—The tonsil exists in all the higher mammals and is recognized by all comparative anatomists. I like Dr. Bliss's scissors very much. In connection with the use of turpentine mentioned in Dr. Baldwin's paper, it occurred to me that I get the best results in such cases from pine-needle oil, used in an atomizer.

Dr. MYLES—Follicular tonsillitis has given me more trouble than any other form. I have found that this condition in early childhood will spread and extend upward into the soft palate

very deeply. I have never been able to use the scissors and knife in these cases as deeply as I would like, because when I seized the tonsil with the forceps it would break loose. I have used the punch forceps to take out quite large pieces. You must work quickly. My experience is that peritonsillar abscess is a certain form of cold abscess which is likely to recur. Two or three times a year the locality undergoes a rapid suppuration for several days. As to the turpentine treatment, I remember a queer experience I had in the South. An old farmer asked me why doctors spent so much time on a little thing like the throat, and added: "When any of my niggers have sore throat, I mix turpentine, sulphur and lard and rub it in, and they get well."

Dr. COULTER—I apprehend that no one instrument will be satisfactory in the hands of all operators. We become accustomed to a certain form of instrument, and each can do better work with his instrument than any other man can, and vice versa. I understood a statement in Dr. Bliss's paper, that he said the top of the tonsil should be a little above the level of the tongue.

Dr. BLISS—That is when the mouth is open.

Dr. COULTER—I have found that the larger part of the tonsil was buried almost under the pharyngeal aponeurosis, often being completely enveloped in the pillars. I am satisfied that the tonsil extends higher up than we have ordinarily thought and that it is almond shaped rather than olive shaped. Dr. Ellegood says that in all these cases the tonsils should be destroyed. I contend that destroying the tissue and leaving it to cicatrize is not necessary, though it may be proper in a certain number of cases. Theoretically it may be all right, but practically it is not. You can not tell how deep into the crypts you are going, and, especially in singers, you leave a cicatricial tissue that makes the case worse than it was.

Dr. BLISS—Dr. Seiss was quite correct in thinking that I did not mean to remove every large tonsil simply because it was large. I referred only to the class of tonsils indicated in my paper, which was on the use of the tonsillotome. I have used the tonsil punch, and it is an excellent instrument, but rather a clumsy one. I think that if Dr. Myles would use the crocodile forceps he would have no trouble in holding the tonsil. These will grasp the tonsil so firmly that it can not slip away. As to the high distribution of the tonsils, I have not found that as a normal condition; it is more a pathologic condition. Such tonsils are more likely to contain material in their crypts. There are many such tonsils as the result of a pathologic process.

Dr. ELLEGOOD—I have never had any difficulty in applying the cold snare to the crypts. I prefer not to use galvanopuncture, except in cases of flat tonsil where the orifices of the crypts are difficult to find. The galvano cautery merely destroys the surface.

MUNICIPAL CONTROL OF DIPHTHERIA.

Presented in the Section on Laryngology and Otology at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, June 1-4, 1897.

BY W. K. JAKES, Ph.M., M.D.

Diphtheria Expert, Chicago Health Department; Instructor in Diphtheria and Physiology, Northwestern Medical School.
CHICAGO, ILL.

The prevention of disease is the province of the municipal health department. The treatment of disease is in the hands of the medical profession whose members have spent time and money to acquire the necessary knowledge, and who stand within that sacred circle of domestic confidence essential in the treatment of disease.

The only tenable ground the municipal health department can take is that of assisting the family physician and there should be no friction between them. The health officer should be careful not to infringe upon the prerogatives of the family physician, who should be high-minded and generous enough to commend the enforcement of public hygiene and respect a power that is greater and broader than his for the prevention of disease.

The improvement of a race or species can only be accomplished during its period of development. No scientific mind can study the effect of ptomain poi-

soning on the growing child and fail to appreciate the importance of preventing contagious diseases in childhood.

No child can reach the same mental and physical development after severe ptomain poisoning. The intellect demands for its symmetrical development the perfect transmission of accurate impressions from the outer world. These come through the five senses. The partial closing of one of these avenues means a lessened power of acquisition and a one-sided mental growth.

No one, not so afflicted, can appreciate the disadvantages of impaired hearing. A child with this defect has a tendency to become slow and morose; is misjudged and misjudges others. Many men and women, who otherwise would have been useful members of society, have been miserable failures because of impaired hearing.

The results of diphtheria ptomain poisoning are not so well known as those of scarlet fever, because that portion of the economy most susceptible to the poison is the vital centers. Hence the difficulty of definitely estimating the insidious and far-reaching effects of the poison. The malignant type of diphtheria may some times be followed, sooner or later, by impaired kidneys, paralysis of the recti muscles causing strabismus, partial nerve destruction, paralysis of the larynx, or a partial arrest of general development. Complete restoration to normal health following any of these conditions depends upon the extent and severity of the injury. As before stated, it is improbable, most often impossible, that these effects may ever be effaced.

Carlo Ceni¹ and Robert J. Berkley have made studies of the lesions induced by the action of diphtheria poison on the nerve cells. Both made the same conclusions. Dr. Berkley says: "From the studies conducted on the cerebra of diphtheritic guinea pigs, it would appear that all severe infections were followed by brain cell degeneration, a degenerative process unaccompanied by inflammatory reaction and a tendency to atrophy and necrosis."²

During 1896 I administered antitoxin to a large number of children in various stages of profound ptomain poisoning with 75 per cent. recoveries; but I noted that quite a number of these died during the following six months. The family physicians diagnosed the causes as Bright's disease, inanition, marasmus, appendicitis, summer complaint, etc. Some of these deaths were no doubt due to gradual brain cell degeneration and necrosis induced by the Klebs-Loeffler toxin.

Diphtheria is both a preventable and a curable disease. A death from diphtheria is now considered by the best physicians in the same light as puerperal fever, namely, the result of ignorance in the physician, or attendant, or both. Could every child have the fullest scientific protection, there need not be a death from Klebs-Loeffler diphtheria. Our duty to the race demands that every precaution should be taken to prevent contagious diseases among children. As long as the child remains at home, the responsibility of giving this protection rests upon the parent. As soon as the child is sent to the school, the store or the factory, it becomes a ward of the State and should have its protection. The prevention of diphtheria then divides itself into, the protection of laboring

¹ Carlo Ceni, *Riforma Medica*, Vol. 1, 1896.

² Johns Hopkins Hospital Bulletin, Feb., 1897.

children, the protection of school children and the children at home.

Over thirty-five thousand children are working for wages in the city of Chicago. In the crowded cars, department stores, and factories they are constantly subjected to contagion and become one of the most prolific means of its spread. They carry the germs home and infect the other members of the family, who may be attending school or kindergarten. These in turn infect their playmates. The doors of our public schools are open to children from any home whether over a stable or on the boulevard, whether it be composed of one room or twenty; whether it be as healthy as sanitary science can make it or filthy as the abode of savages. The public school room below the grammar grade is a perfect clearing-house for the exchange of mouth germs. The average child is not troubled by the niceties of older people, who, however generously inclined, do not exchange eatables and personal effects with such freedom as is done in school. Children at home are usually infected by those members of the family who are at work or in school; hence the prevention of the spread of contagion in the school and factory is one of the most efficient ways of protecting the home.

Competent medical supervision and inspection of schools and every place where there is child labor, offers a great field for work the benefits of which will extend beyond those directly affected. There are many pupils in our public schools with defective sight and hearing that could easily be remedied if discovered early and properly treated, while child labor is employed under conditions the heathen nations would not tolerate.

The State has every right to throw rigid restrictions around child labor for her own protection. Unless done in harmony with the laws of mental and physical development, it works a two-fold injury; first to the child itself, and second, to the coming generations.

Medical inspection should be done with the organized system that characterizes scientific work. The services of the best specialists should be obtained to direct the efforts of the medical inspector, for the most valuable results await the adoption of scientific methods in the formulation of laws governing child life.

However valuable it would be in other diseases, medical inspection would derive its most brilliant results in the prevention of diphtheria. During the winter season when it is most prevalent, the inspector should instruct teachers and employers in the symptoms of infection. He should make cultures from the throats of those who have been exposed to contagion as well as from returning convalescents before permitting them to re-enter school.

Some of our cities are a long way from the adoption of scientific medical inspection and until municipal authorities see the feasibility of such methods, we must control diphtheria with the best means we have at hand.

During the winter of 1895-96 the southern half of the city was put in my care by the Chicago Health Department, to assist in controlling a threatened epidemic of diphtheria.

Having given ten years of special study to the disease, and tried faithfully every remedy that my judgment approved, or the experience of others recommended, I was well prepared to judge of the value of antitoxin. The experience of that epidemic taught

me two things: The value of antitoxin as a curative agent, and the importance of an early bacteriologic diagnosis as the most important measure for the prevention of the disease.

If within a few hours of the first call of the physician to see an inflamed throat, the infectious nature of the disease is known and the child isolated, the spread of the infection may be stopped. Those who have seen families, schools and whole communities infected before the malignant nature of the disease was discovered, will appreciate the importance of having infection stopped at the first case.

The bacteriology of diphtheria demonstrates the great rapidity with which the Klebs-Loeffler bacilli multiply under favorable conditions. The microscope has enlarged our vision and enabled us to see these germs, while scientific methods have formulated laws governing their existence. It is the application of these laws that gives us control of this disease; hence the successful prevention of diphtheria depends upon a thorough knowledge of the bacteriology of anginas.

All anginas manifesting membrane should properly be described as diphtheria, since its derivation is from the Greek word meaning membrane. However, since the Klebs-Loeffler bacillus has been found to be the chief cause of mortality in anginas, only those cases where it is present are usually called diphtheria.

The germ or germs which are the chief causative factors in producing this disease are most sensitive to environment, by which is meant all the conditions influencing the life of the germ as well as that of the patient who furnishes the soil for invasion.

Environment is continually changing. No two consecutive days have the same amount of sunshine, heat or moisture. Each season brings conditions which have their influence on the germs of the membranous anginas. With a knowledge of these facts it is readily comprehensible why the anginas of one year, or of one season, should differ from those of another. If the conditions are favorable to the virulence of a certain germ, it will prove the causative factor of the anginas of that year, subsiding into a secondary position with new conditions which favor the virulence of another germ.

The bacteriology of the anginas of 1896-7 has presented many interesting differences from those of last year. At that time, nearly 75 per cent. of all inflammations, including those causing stenosis of the larynx, were due to the Klebs-Loeffler bacilli. At the close of this year, it is some member of the streptococci family that most often causes the invasion.

Following its invasion, each germ has a definite train of clinical symptoms characteristic of itself, and were it not for the fact that there are so many mixed infections, there would be little difficulty in making a diagnosis without the microscope. But it is seldom the case that a culture reveals only one germ; others are nearly always present, it may be as accessories in a minor degree to one germ causing the lesion.

In every mouth there are a number of pathogenic germs which are impotent except when favorable conditions are presented for multiplication. If constitutional resistance becomes weakened toward any one of the germs present, that one may become the exciting cause of inflammation.

This fact must be kept in mind when examining cultures microscopically, namely, to determine the invading germ and treat the case accordingly. The malignancy of a germ is usually determined by the

rapidity of its multiplication. When a germ acquires this malignancy, it is probably because the patient's antitoxic power is reduced. For instance: The case of a child was diagnosed as Klebs-Loeffler diphtheria and antitoxin administered followed by typical reaction and recovery. Three weeks later a second inflammation occurred, culture showing mixed infection with Klebs-Loeffler bacilli present. Antitoxin was again injected with no reaction. The case followed the usual course of a streptococcal angina. The patient was already antitoxinized against the Klebs-Loeffler bacilli, and although the germ was present, it had but little influence in the inflammation.

In laryngeal inflammations the staphylococcus causes simple spasmodic laryngitis; the streptococcus a stenosis of long duration, sometimes requiring intubation or the substitution of tracheotomy. If the Klebs-Loeffler bacillus causes the stenosis, it is possible to be as positive of the action of antitoxin as of morphin; while the ratio of mortality becomes 15 to 20 per cent. instead of 80 to 90 per cent.

The staphylococcus is nearly always present in the fauces, and is always present in slight inflammation of the tonsils. The crypts of enlarged tonsils contain them and a slight cold causing congestion of the mucous membrane produces the necessary condition for disease.

Occasionally the staphylococcus takes on considerable malignancy, the temperature rising to 104 and 105, causing considerable constitutional disturbance. It is the invasion of this germ that results in simple spasmodic laryngitis. One of the chief characteristics is the short duration of the inflammation.

The streptococcus is the next germ in malignancy, and has a wide range of virulence depending upon the conditions under which the invasion takes place. The point of invasion may be in the tonsils, but the entire tissues of the fauces are more likely to be involved, producing a dark red appearance with little or no membrane for thirty-six or forty-eight hours. The membrane is always small in proportion to the amount of inflammation. There is a tendency for the inflammation to spread back of the tonsils up into the posterior pharynx, invading the Eustachian tube, causing great difficulty in swallowing, also impairing the hearing. This is the most painful of all anginas, the most difficult to relieve and the slowest to recover. While the temperature in staphylococcus infection is high in the beginning and reaches a maximum in twelve or twenty-four hours, the temperature in streptococcus infection gradually increases to 102 and 103, remaining stationary for two or three days until influenced by treatment.

Symptoms are neither so apparent nor so alarming in the invasion of the Klebs-Loeffler bacillus. The germ seems to have an anesthetic action locally, and acts as a constitutional depressant. There may be little or no pain. The patient will be quiet, gradually going into a stupor. On examination of the fauces, membrane will be present either following primary inflammation or at first inspection. True Klebs-Loeffler diphtheria is the least painful of all anginas. The invasion usually takes place in the fauces, spreading to those parts of the mucous membrane which are susceptible, such as the nasal passages, the posterior fauces and the trachea.

During the past year the pseudo-bacillus has frequently appeared in the cultures. My observation leads me to think this germ is the Klebs-Loeffler

bacillus changed in its morphology owing to the soil upon which it grows. My reasons are as follows:

1. Cases have resulted fatally with this bacillus as the invading germ, giving every clinical evidence that death was caused by ptomain poisoning.

2. The genuine Klebs-Loeffler diphtheria has been contracted directly from cases of pseudo-diphtheria.

3. The morphologic change between the pseudo- and the Klebs-Loeffler bacilli is no greater than is seen by growing the Klebs-Loeffler bacilli on blood serum and agar agar; or the change which the Klebs-Loeffler bacillus undergoes from the beginning to the end of a case of true diphtheria.

For these reasons, I advise the administration of antitoxin in cases where the pseudo-bacilli appear, and in most of these cases typical reaction follows.

Temperature is considered an important indication of the gravity of a disease. This rule must not strictly govern anginas, as the highest temperature is caused by a germ of the least malignancy, namely, the staphylococcus. In the worst form of Klebs-Loeffler diphtheria there may be not only an absence of increased temperature, but it is sometimes sub-normal.

The accompanying tables of the clinical symptoms of diphtheritic diseases during the first, second and third thirty-six hour periods are not assumed to be perfect, as they are compiled from a limited number of years' experience; but it is hoped they will form a substantial basis for further observation.

CLINICAL SYMPTOMS. First Thirty-six Hours.

Diphtheritic diseases.	Temperature.	Local condition.	Mental.	Urine.	Bowels.
I.—Staphylo-diphtheria.	Rises rapidly to 103, 105.	Swollen tonsils with membrane appearing around follicles. Headache; pain.	Bright.	Diminished; highly colored.	Constipated.
II.—Strepto-diphtheria.	Rises gradually to 101, 103.	Invasion usually extended to large part of pharynx, posterior nares; membrane does not form rapidly; mucous membrane congested; covered with thick mucus; more pain than I.	Fretful and easily irritated.	Diminished; highly colored.	Constipated.
III.—Klebs-Loeffler Diphtheria.	1. Mild.	99 to 101. Redness with little or no swelling; small amount of white membrane; slight pain.	Normal.	Normal.	Constipated.
	2. Moderate.	99 to 101. Redness over more extended area than I; any part of pharynx, larynx and trachea.	Normal.	Normal or less in quantity.	Constipated.
	3. Malignant.	99 to 101. Redness, but not painful as streptococcus infection; may be large or small amount of membrane in sight.	Dull; care-less.	Normal.	Constipated.

Second Thirty-six Hours.

Diphtheritic diseases.	Temperature.	Local condition.	Mental.	Urine.	Bowels.
I.—Staphylo-diphtheria.	Decreasing, 101.	Membrane white with definite edges; less congestion.	Normal.	Normal.	Open; responded to cathartics or enemata.
II.—Strepto-diphtheria.	Stationary, 102, 103.	No improvement; thin membrane; tonsils will be covered if large; much pain in swallowing.	Fretful; loss of sleep.	Dark color.	Inactive.
III.—Klebs-Loeffler Diphtheria.	1. Mild.	Stationary, 100, 101. No improvement unless antitoxin has been given; membrane formed.	Normal.	Normal.	Active.
	2. Moderate.	Stationary, 100, 101. No improvement; membrane formed. Process stationary.	Normal.	Albumin. (?)	Constipated.
	3. Malignant.	Stationary, 100, 101. Membrane extending, glands may be involved.	Stupor.	Albumin. Less.	Normal or inactive.

Third Thirty-six Hours.

		Third Thirty-six Hours.				
		Normal.	Nearly normal.	Normal.	Normal.	Normal.
I.—Staphylo-diphtheria.						
II.—Strepto-diphtheria.		Decreasing.	Beginning to improve if no abscess has formed.	Normal if no pus formation	Normal.	Normal.
III.—Klebs-Loeffler Diphtheria.	1. Mild.	Decreasing.	Improvement; membrane disappearing
	2. Moderate.	May change to 1 or 3 (III).
	3. Malignant.	Stationary or decreasing.	Membrane extending or glands enlarged; bleeding at nose; heart irregular; fetor from membrane.	Stupor, Albuminuria.	Paralyzed.

It may be observed from these tables that the symptoms which are most likely to attract the parent's attention to the child's throat, namely, pain and fever, are produced by the most common and least harmful germs. The Klebs-Loeffler bacilli may be present without any modification of clinical symptoms until the system is permeated with ptomain, and evidence of ptomain poisoning appears. If the nature of the disease has not been discovered and antitoxin given before this stage is reached, the chances for recovery are greatly reduced—if not entirely shut off—for, as before stated, the action of diphtheria poison is destructive. Antitoxin can not restore destroyed kidney tubules, blood corpuscles or nerve centers. It must be given in time to prevent this destruction. A culture from the throat will show in a few hours if the germs are present, and upon the proper use of the culture, more than anything else, depends the control of diphtheria. With it, we can tell not only the presence of the germ in those who are sick, but can estimate the exact limit of infection in those who have been exposed to the contagion.

The earlier the diagnosis the greater its value. To get an early diagnosis without infringing on the rights of the family physician is the problem which the health department must solve.

In the City of Chicago, and I presume it is more or less true elsewhere, the major part of practice is in the hands of physicians who graduated in medicine before there was a department of bacteriology. These physicians are the first to see cases and they are the proper ones to take cultures. If they have to call in an expert to make the culture, or have it done at an extra expense, the occasions when they find they were needlessly alarmed will cause them to neglect this important measure.

I have found that physicians are influenced in making a culture by the convenience with which they can have it done. The introduction into the culture outfits of the Chicago Health Department of the small metal boxes for culture media has had much to do with the large number of cultures obtained by the department. They were devised by me to meet the requirements of the general practitioner. Properly prepared, they will keep indefinitely. They are strong, light and small, so that several can be carried in the pocket or bag without taking valuable space. After inoculation the box can be placed in the watch pocket near the body and incubation begins at once.

What is of greatest importance, these boxes may be examined many times during the development of the culture without affecting its progress. This is done by the Klatsch method—the pressing of a clean cover glass on the surface of the serum. A sufficient number of the germs will adhere to be fixed and stained, at the same time preserving their characteristic arrange-

ment. Thus the rapidity of the growth can be noted and something of the malignancy ascertained. A diagnosis can often be made as soon as the box can be examined. When this can be done it is of importance in indicating malignancy.

During the past year I have made an immediate diagnosis in about one-third of the diphtheria cultures; another third required six hours incubation, and the remaining third ten hours.

A physician can carry one of these boxes in his pocket and when called to a suspected case of diphtheria, with a little absorbent cotton on a probe, he can inoculate the box and prescribe treatment. Diphtheria or the health department need not be mentioned. By his next visit he is fortified with a positive diagnosis. If he has to send to a station for a cumbersome outfit, inoculate and send it to a distant laboratory and wait eighteen to twenty-four hours for a diagnosis he is placed in an embarrassing position. His procedure has alarmed the parents and his uncertainty will not inspire confidence. If the report shows no necessity for the alarm, confidence in his judgment will not be strengthened and he will naturally avoid a repetition of the occurrence.

To test the efficacy of convenient methods, a sub-laboratory was established at my office by the health department during the past winter for the use of the physicians on the South Side.

Until December 15 there was only now and then a sporadic case of Klebs-Loeffler bacilli among the numerous cultures showing streptococci infections. Then in three days I had nineteen rapidly growing cultures of the Klebs-Loeffler bacilli taken from patients among the wealthy families of Kenwood. The family physicians in these cases received their diagnoses, some of them in two, all of them within six hours; the patients were immediately isolated and given antitoxin. All recovered and there was not a second infection from any of the cases as far as could be learned. Several deaths occurred in the practice of those physicians who did not use a microscope to make a diagnosis.

During the past season I have made nearly five hundred bacteriologic examinations. About 30 per cent. of these revealed the Klebs-Loeffler bacilli. The records show that those physicians who availed themselves of the bacterial diagnosis had no deaths from diphtheria.

No small part of this excellent result was due to the high quality of the antitoxin that was used.

The health department renders the physician valuable assistance when it places within his reach a reliable grade of serum. Not having the government guarantee possessed by the European physician the next best thing is to possess the guarantee of our municipal health department, who conserves its own interests in protecting the interests of the people. The health authorities can acquaint themselves with reliable manufacturers of antitoxin and in the laboratory they have the means of testing its quality. Antitoxin should be furnished to physicians at as low a rate as possible. Diphtheria is emphatically a disease of the poor. To avoid delay and not endanger life a physician must often furnish the antitoxin and wait for his compensation, if he gets it at all.

The injection of serum by health officers should be avoided in all cases where it can be done by the family physician. Free dispensaries, hospitals and medical colleges do enough to depreciate the value of a

doctor's work without the health department contributing its services.

Some producers of antitoxin advise its administration without waiting for the bacteriologic diagnosis. This may be justifiable in laryngeal cases, but in not one case out of a hundred will the interests of the patient suffer if a culture can be made in four hours. Antitoxin is a highly organized product of unknown properties requiring the highest skill in its manufacture, and can only be produced by carefully followed rules requiring months of work and involving large expense. The failure of a single step in the long process will affect the product. This remedy is injected directly into the tissues and is absorbed by the blood. The action is so rapid that if unfavorable one patient is beyond hope before any known means can counteract the effects. These facts make it imperative that the utmost consideration should be given the subject of when and how to administer antitoxin. I have taken the serum myself and know its immediate effects are painful. I have also seen most alarming symptoms follow its administration. Hence the indiscriminate injection of antitoxin in cases of angina is dangerous, unjustifiable and unscientific.

Every city has its own problems to solve. In evolving a plan for controlling diphtheria all conditions of municipal life must be considered. Grades of diphtheria differ in New York, Paris, London and Chicago, as the environment of those cities differ. If the mortality of diphtheria in Chicago is lower than that in New York it is only fair to say that it is probably due more to the less crowded condition than to superior equipment.

Our position of health commissioner is a political one with a term of but two years. This is a short time to institute and carry out any elaborate scheme of hygienic reform. But it is long enough to set in motion plans of work whose beneficial effects will not permit them to be dropped by the next administration.

The municipal control of diphtheria then means:

1. The enforcement of those hygienic laws which will increase physiologic resistance and thus remove predisposition to the disease.
2. It must protect children from contagion by competent medical inspection in schools and public places of work.
3. It should furnish physicians convenient means for early bacteriologic diagnosis.
4. It should obtain and furnish the best possible quality of antitoxin.

4316 Greenwood Avenue.

DISCUSSION.

Dr. REYNOLDS—It seems to me that the logical result of all this antitoxin and germ study is that every physician who visits families and comes in contact with them should be able to make a diagnosis in from two to four hours. It is the function of the department of health to prevent disease.

Dr. ROOR—This very important subject concerns not only ourselves as specialists, but the general practitioner as well. One point has not been touched upon, and that is the necessity of having these cultures made and the bacteriologic examinations continued after the apparent symptoms have cleared up. The difficulty is that after the case is apparently well the children are allowed to go to school and about the streets while they are perfectly capable of infecting others. In Hartford we insist that every case shall be reported at once to the health board. Test tubes are kept, on ice, in the leading drug stores. When a physician sees a suspicious case he can drive to the nearest drug store, get a test tube, make his culture and have it sent at once to the health board. A record of the case is made and kept, and is inspected by the health inspector, and before the child is allowed to go out it must be demonstrated that there are no more bacilli in the throat. When the throat is apparently well he may still infect others by expectoration, etc.

Dr. VANSANT—I do not think that any such discussion should proceed without a protest against a diagnosis of diphtheria based solely on the presence of the Klebs-Loeffler bacillus. It is not a simple thing to diagnose a case as diphtheria, and we should proceed carefully. A diagnosis based on the presence of this bacillus alone is not necessarily correct. I made a series of cultures from 100 patients last winter, and with the aid of our bacteriologic department examined the secretions in chronic nasal catarrh. I excluded every case that had any clinical signs of diphtheria. One of the first cases I sent was rhinitis. A report came back that typical Klebs-Loeffler bacilli had been found and the case must be isolated at once. The case was a true atrophic rhinitis, but every time I examined I got a beautiful culture of the bacillus. There was no sign of diphtheria whatever. From 25 to 50 per cent. of the cases of chronic nasal catarrh contain the bacillus. I protest against isolating cases simply on the bacteriologic examination. We should also have well-marked clinical signs.

Dr. JURIST—In a town not many miles from here two police surgeons made cultures from each other's throats and sent them to the city bacteriologist. They were promptly quarantined the next day, though there was no sign of sickness. When physicians depend on one point in any diagnosis they fall in error. We have also in laryngology attached too much importance to bacteriologic investigation. I believe that in 95 out of 100 cases the disease can be determined without bacteriologic investigation. Isolate your patient for a day or two and you will often see that a case can appear like diphtheria and not be diphtheria.

Dr. RANDALL—The nasal cases are not so apt to convey infection, and yet I know of many a case that has originated in this way. I know a resident who had such a condition in his nasopharynx, and he was responsible for several cases of diphtheria in the hospital and finally had a plain case of the disease himself. Cases are certainly infectious in that stage and call for recognition. The difference between faucial and nasal cases must be borne in mind.

Dr. JAKES—The Klebs-Loeffler bacillus may be in many throats without producing diphtheria. Physical resistance is what prevents children from taking diphtheria. About this time of year most children have the bacillus in their throats without producing diphtheria. In winter the conditions are more favorable for its occurrence. Great care is necessary. A person who has the bacillus in his throat may not have diphtheria, but he may come in contact with a child who is susceptible and cause the death of the child. I have known mothers who had this condition of the throat to inoculate their children and cause their death. For the protection of the physician, he should know the origin of every case of angina that comes under his care. He can then put the bacteriologic diagnosis with the clinical symptoms and know what the disease is.

REMARKS UPON THE SURGICAL TREATMENT OF MALIGNANT DISEASE OF THE LARYNX.

Presented to the Section on Laryngology and Otology, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY D. BRYSON DELAVAN, M.D.

NEW YORK.

While operations for the cure of malignant diseases of the larynx have generally resulted in shortening rather than lengthening the lives of patients so operated upon, the experience of the past few years in certain parts of the world has been somewhat encouraging. Indications are beginning to appear which suggest that for this class of patients there exists a not entirely unpromising future.

Within the past two years several papers have been published in which the proportion of successful operations has been unusually large, and while the actual number of patients operated upon has been too small to establish any positive conclusions, and the dates of most of the operations have been too recent to admit of a complete study of the cases themselves, there can be no question that the work recorded in them is, on the whole, worthy of careful consideration. The varieties of operation which have lately challenged atten-

tion by reason of the improvements which they have offered may be divided into three groups: 1, thyrotomy, with or without partial laryngectomy; 2, complete laryngectomy by the method adopted in Solis-Cohen's case; 3, complete laryngectomy in cases of extensive laryngeal disease with glandular involvement. Examples of all three are beginning to multiply to such an extent that it will not be long before we shall have a collection of details sufficient to afford a fairly positive knowledge of their real value, together with a fund of technical knowledge relating to the subject which can not fail to be of material aid for future guidance.

A short consideration of these methods may not be without interest. The first variety, while advocated by many surgeons here and abroad, has been studied and practiced in this country chiefly by Prof. Clinton Wagner of New York, and by Mr. H. T. Butlin and Dr. Semon in London. It consists in performing thyrotomy and removing as much of the diseased tissues as may be necessary. Mr. Butlin, in the main agreeing with many of the best surgeons of the day, has advanced the following propositions:

1. Every malignant growth of the larynx of intrinsic origin which can be dealt with should be treated by an operation in the absence of a decided indication to the contrary, and the operation should be performed with the least possible delay.

2. Every tumor of the larynx suspected to be malignant, of intrinsic origin, of limited extent and apparently within reach of free removal, justifies an exploratory thyrotomy in a suitable patient, in the absence of infiltration of the surrounding structures and of affection of the lymphatic glands.

The method of operating pursued by Butlin and Semon has been described in their published writings. It applies distinctly to cases in which the disease is absolutely confined to the interior of the larynx. Preliminary tracheotomy is done with the insertion of the tampon canula and its careful adjustment. The anterior part of the thyroid cartilage is laid bare with scalpel and raspatory, it is opened exactly in the median line, and the two sides of the larynx are held apart, preferably with two strands of strong silk inserted through the anterior parts of the lateral wings of the thyroid. After the latter has been split open, undue violence in holding the halves apart must be strictly avoided. At this stage it will generally be necessary to protect the parts from mucus and saliva by packing the lower part of the pharynx with a large septic sponge secured by a string and passed through the laryngeal wound upward. There are two recommendations upon which Semon lays special stress: 1, the surgeon should be provided with a forehead reflector and a good light, and as has already been suggested by the writer for deep operations in the pharynx, he should if possible have at hand a small two-to-four-candle power electric lamp, to be used for the purpose of securing the best possible illumination of the interior of the larynx for the detection of every possible bit of diseased tissue; 2, before he begins the removal of the growth the whole side of the larynx to be operated on should have applied to it a 5 per cent. solution of cocain, for the purpose of contracting the capillaries on that side and preventing parenchymatous bleeding, which otherwise is sure to interfere with and greatly prolong the removal of the growth proper, while at the same time it may allow suspicious portions to remain behind. The importance of the

two above mentioned measures is strongly insisted upon. The field of operation having been thus prepared, the diseased soft tissues are thoroughly removed to at least half an inch from the periphery of the growth, and if necessary the underlying cartilage is scraped or even removed, the base being firmly scraped with a sharp spoon. The use of the galvano-cautery will seldom be required. Every source of bleeding having been stopped, the whole interior of the wound is dusted with pulverized iodoform, or with iodoform and boric acid in equal parts, and the tampon canula is immediately removed. The whole of the wound is then covered with cyanid or iodoform gauze.

In cases where the more extensive resection of the thyroid or even extirpation of one-half of the larynx is contemplated, the parts of cartilage to be removed should be freed from their perichondrium and from the surrounding soft parts by means of an elevator. In other respects the operation is the same, only more extensive than mere thyrotomy with removal of soft parts. It is generally not necessary to prophylactically ligate the laryngeal arteries. Where the epiglottitis or the aryteno-epiglottidean folds are diseased, the best means of access to them is sub-hyoidean pharyngotomy.

For after-treatment, both Wagner and Butlin immediately remove the tampon canula, and from that time use no tracheal canula whatever, and the wound having been dressed as above described the patient is not propped up in bed, but is placed horizontally on the side corresponding to the half of the larynx operated on with one small pillow under the head. Instead of plugging the wound with gauze as formerly, Mr. Butlin dusts it at least twice daily for the first few days with the antiseptic powder by means of a powder insufflator. The application can be made to the best advantage when the patient is swallowing, as during the act of deglutition the wound in the neck is separated sufficiently to admit the end of the powder-blower, so that the powder may be thrown directly against the raw surfaces, which should be thoroughly covered by it. The external covering of cyanid or iodoform gauze should be removed as often as wet by secretion. Although nutrient enemata may be required for the first few days, the experiment may be tried on the day of the operation or soon thereafter, of allowing the patient to attempt to drink a little water while leaning with the upper part of the body well over the edge of the bed. In case of any impediment to the closure of the larynx during this act, the water will run directly out of the wound and no harm result; should the experiment succeed milk may at once be taken in the same way, and the necessity for rectal feeding avoided. The external wound gradually closes by granulations, which may have to be stimulated by applications of nitrate of silver.

Turning now to the method of operation classified as number two, we find that a distinct advance has been made in the treatment of cases requiring complete extirpation. It was first proposed and practiced by Prof. J. Solis-Cohen of Philadelphia. The patient upon whom he originally employed it in 1892, is still living and well. In this operation, as in several similar to it, the larynx was completely removed and the severed end of the trachea brought to the external edges of the cervical incision and there retained, communication between the lungs and the pharynx being thus totally and absolutely cut off. The great advantages of this plan over the usual methods are:

1. The danger to life from inspiration pneumonia is greatly lessened, owing to the shutting off of the mouth from the trachea.

2. Swallowing is accomplished with great ease and as freely as under ordinary circumstances.

3. In at least three cases thus operated upon, the power of phonation has been acquired with a voice fully as satisfactory as that produced by any artificial appliance, and without either the inconvenience and discomfort of an artificial larynx or the danger to the adjacent parts from the irritation of its presence. The mechanism by which phonation is accomplished in these extraordinary cases has not been explained. Cohen's patient is able to make his voice distinctly heard from one end to the other of the great hall of the New York Academy of Medicine.

4. The comfort of the patient is greatly increased, and the disfigurement of the other operation and the wearing of the artificial larynx largely done away with. It is entirely probable that under certain conditions, this method will prove to be the most satisfactory for complete laryngectomy of any yet proposed, and it is to be hoped that it may be given a sufficient trial to prove whether or not the cases already reported have been but the result of a happy accident rather than the first illustrations of a definite rule.

As to the third variety of operation it has often been insisted that in order to insure success, malignant disease of the larynx must be treated as early in its history as possible, and at least before involvement of the neighboring glands has taken place. Unfortunately in the history of the past early operation has not always saved life, but on the other hand several eminently successful cases have been in patients who suffered from a tolerably extensive condition of disease. The management of cases of extensive laryngeal disease, therefore, becomes a matter not only of great importance but of lively interest, especially when it is remembered that perhaps a majority of patients are not seen by the specialist or surgeon until the disease has made considerable progress, and the time most favorable for operation has passed.

Several years ago operations were attempted upon such patients with only here and there an exception to the inevitably and immediately bad result. Subsequently they were generally left to their fate. Of late, under the influence of improved methods and increasing knowledge, a hope, a small hope indeed, but worthy of all encouragement, has been aroused by the excellent work of several men. Prominent among these may be mentioned Mr. Watson Cheyne of King's College Hospital, London, whose efforts in this direction are now attracting much attention, and who in his admirable Lettsonian Lectures (*Lancet*, February 15 and 22 and March 14, 1896,) upon "The Objects and Limits of Operations for Cancer," delivered before the Medical Society of London last February, says: "As compared with cancer in the breast, the disease in the throat is in some ways more favorable for cure; in other ways less so. Primary disease of the breast is by far the more favorable of the two, for there it is fully exposed to view, and there is plenty of room for its free removal without endangering important structures. In the mouth and throat, on the other hand, the disease is close to if not involving many important parts, the space in which one has to work is very limited, any considerable margin of healthy tissue can not be obtained, and the early spread of the cancer to muscle, tends to distribute it over a considerable area.

In the throat, moreover, the disease is much less favorable for operation, because the septic elements comes into play, and thus instead of having to do with an operation in the breast where the mortality is practically nil, we have to face very considerable risk of death from septic disease. On the other hand, cancer of the mouth and throat is more favorable as regards the glandular deposits, for in the neck we have an extensive glandular area exposed to view which can be much more thoroughly dealt with than in the case of the breast. It is true that many surgeons look on the glandular trouble as a most serious part of the disease. With this I do not agree. In another respect cancer in the throat is more favorable than in the breast, namely, that in it metastatic deposits are infrequent."

As to the neighboring lymphatics, Cheyne believes that they should be removed as in cancer of the breast. It is seldom that no enlarged lymphatic glands can be felt in these cases, and usually they are of considerable size. Whether they can be felt or not, the lymphatic area should be cleaned out. Unless the lymphatic enlargement is very extensive or adherent to a variety of structures in the neck, and not merely to the sheaths of the vessels the operation will be more thoroughly done and the patient will have a better chance of recovery and cure if enlarged glands are already present.

With regard to preliminary tracheotomy, Cheyne, agreeing with many other excellent authorities, does not believe in the insertion of the tube several days prior to the performance of the main operation. Personally I do not think his ground upon this question well taken, the objection being that in three or four days after the insertion of the tube there will be a collection of septic matter around it which may get into the trachea after the performance of the main operation. Such an accident could probably be avoided by extending the time between the two operations to ten days or more. It is desirable, however, that this question, namely, when preliminary tracheotomy should be performed, should receive more careful attention than has hitherto been accorded it, as it is without doubt an important factor in the patient's welfare.

These three varieties of operation just described may be said to finally represent the most recent additions to our present resources for the surgical relief of malignant disease of the larynx.

Turning now to the statistics of these and similar operations performed upon the larynx, we find according to a recent valuable article published by Schmiegelow of Copenhagen, in *Gouguenheim's Annales* for April, 1897, that during the past six years the mortality resulting from extirpation of the larynx has been materially diminished. Thus up to 1880, according to Holmer, the mortality was 42 per cent. Tauber reports a rate of 60 per cent., following total extirpation of the larynx between 1866 and 1890. Between 1880 and 1888 Schier found that the rate had fallen to 34 per cent. Since 1890, however, the reports are much more hopeful, for the same observer finds that the rate during that period has been reduced to 22 per cent. Schmiegelow, carrying the reports up to the present time, finds that the percentage of cures since 1890 has been 13.5 per cent., and of immediate mortality 18.7 per cent.

I earnestly wish that these flattering statements as to the improved statistics of this class of operations could be accepted as accurate and reliable. Undoubt-

edly in the cases of certain individual operators, who like Hahn, Butlin, Schmiegelow and some others, have faithfully and without reserve reported all of their cases good and bad alike, we are able to gain from their reports deductions of genuine value. It is both discreditable and unfortunate, however, that many operators have failed to publish their unsuccessful cases and have only reported such as have resulted well. This, I am sorry to say, has been particularly the case in our own country. Two years ago, the writer in the course of preparing an article upon this subject, wrote to the principal surgeons of the United States asking for a statement of their results. The answers were so incomplete and unsatisfactory that he abandoned the attempt. One surgeon who had operated four times with three speedy deaths, entirely omitted to mention his failures, while the successful case was reported in full.

Time and again the operation has been attempted under unfavorable conditions and by unskilled but venturesome men, whose rashness has quickly robbed the patient of what little hope belonged to him, and who having nothing creditable to report, have avoided publicity. If the whole story were to be told it is probable that the statistics in this country would be discouragingly bad.

It can not be insisted upon too urgently that carcinomatous cases requiring laryngectomy are desperate at the best, both as to immediate and ultimate results, and that with our present limited knowledge of the subject, no amount of caution, however great, will avail in preventing a high percentage of failures. With the sources of danger so numerous, constant and subtle, it is impossible that too great foresight or experience be brought to bear against them, or that the urgency of this demand be over-stated. Doubtless the best preparation for the work on the part of the surgeon would be a thorough knowledge of operations upon the tongue, neck and lower jaw in general. In the after-care of the patient also it is not by any means enough that the watchers should be ordinarily qualified in the care of severe surgical cases. Nothing short of special fitness in the department of this particular class of cases will yield the best results.

Next, such accidents as the entrance of septic or foreign matters into the air passages must be carefully guarded against. The use of the esophageal tube when entrusted to inexperienced hands has often been the cause of disaster. This part of the management as proved by the records of failure, requires most careful handling. Another dangerous and preventable accident is the poisoning of the patient by the antiseptic dressings, among which iodoform has been the principal offender. The substitution for it of a mixture of equal parts of powdered iodoform and boric acid, or of the compound tincture of benzoin has been attended with success.

In reviewing the recent progress in the treatment of malignant disease of the larynx, and in studying the manner in which these advances have been made, it must be apparent that nearly all have been the result of long and close study of the subject by accomplished surgeons, whose opportunities for clinical study have been unusually great. The time has long passed when an unsuccessful attempt at laryngectomy by one not fitted for the work can bring anything but reproach to the operator and discredit to the operation.

I am strongly of the opinion that, for a time at least, both the welfare of the patients operated upon and

the interests of science demand that the indiscriminate performance of capital operations upon the larynx should cease. In most great centers there are individual surgeons or groups of operators who are especially well fitted both by personal qualifications and hospital facilities for the successful performance of this work, as has been proved in many cases by the records which they have already made. Let such men surround themselves with the proper assistants, let them systematize their efforts and use all the diligence in the perfection of appliances and methods and in the study of the cases under them, and keep careful and accurate record of everything pertaining to the history of their work. Then resign to them temporarily the care of as many cases of laryngeal cancer as possible. When a sufficient amount of material has been collected, we shall learn whether the radical extirpation of laryngeal epithelioma is unjustifiable, or whether, as we have the best reasons for hoping, it is likely to establish for us a reliable means of cure.

Finally, with the best results obtainable, it should not be forgotten that in this disease surgery is, and probably always will be, a forlorn hope, and that until we have discovered some better method of dealing with it, the results of operation, even under the best conditions, will fall far short of a perfect means of cure.

DISCUSSION.

Dr. COHEN—In my opinion much of the success of the case depends upon the attention given to the patient after operation. Operation is of course very important, but the best operation will fail if the patient does not receive the proper after-treatment. I am certain that a number of the cases I have seen could have been saved with proper care. The patient requires not only to have the surgeon within immediate call, but also the laryngologist. The great mistake is made when the laryngologist abandons the case to the surgeon, for the surgeon is not always familiar with the emergencies that may occur in such cases. Even if the laryngologist is not able to perform the operation, he should be in constant attendance with the surgeon until the patient is out of danger.

Dr. MACKENZIE—The surgical treatment of laryngeal cancer has resulted in failure in the past because the methods employed have not been sufficiently radical. Thyrotomy, partial and complete extirpation of the larynx have fallen far short of success simply because they have not completely removed the disease. There is but one rational treatment for cancer of the larynx. Early total extirpation of the organ together with its neighboring lymphatics and glands whether the latter be apparently diseased or not, is the only possible safeguard against local recurrence and metastasis. By no other method can we give the patient a reasonable assurance of a permanent lease of life.

The time will surely come when the conscientious surgeon will consider that he has fallen far short of his duty to his patient and himself if he does not in the treatment of cancer of the larynx, no matter how circumscribed the growth may be, remove not only the entire organ, but also the neighboring lymphatic area. Then and not until then will we have more favorable statistics and prognosis in cancer of the larynx. Then, and not until then, will the medical historian chronicle a real advance in the management of this terrible disease.

Dr. MYLES—I think the high death-rate is because the general surgeon does not know enough about the after-treatment of these cases. We have our laws as to laryngeal trouble and things germane thereto, but we should have the assistance of the general surgeon and let him do the cutting. In a case which Dr. Mackenzie and Dr. Halsted had, after the larynx was extirpated there was no recurrence at all. They decided to take out the whole larynx and found by the microscope, cancer on the opposite side which had not been evident before the operation.

Itching of Urticaria.—Distilled water 450 parts; cherry-laurel water, 50 parts; chloral hydrate, 5 parts; cocain hydrochlorate, 3 parts.—*La Provence Médicale*.

SOME DEFECTS OF SPEECH; THEIR CAUSE AND TREATMENT, WITH EXHIBITION OF CASES.

Presented to the Section on Laryngology and Otology, at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY G. HUDSON MAKUEN, M.D.

PROFESSOR OF DEFECTS OF SPEECH IN THE PHILADELPHIA POLYCLINIC AND LARYNGOLOGIST TO ST. MARY'S HOSPITAL. PHILADELPHIA, PA.

The first case is one of defective speech due to a cleft palate. The boy, J. C., was born in Ireland eleven years ago with a cleft running back through the lip, alveolar arch, hard palate and soft palate. The hare-lip was beautifully closed by Dr. Hamilton of Dublin, when the child was 7 months old. He always had great difficulty in swallowing and his speech was entirely unintelligible. When he was 9 years of age Dr. John B. Roberts of this city did a very successful operation for closing the palatal cleft. This made the boy comfortable in every way, but it did not improve his speech to any appreciable extent. Even had he been given a perfect palate and perfect lips his speech would still have been defective, because for nine years the other organs of speech had been trying to adapt themselves to very imperfect conditions, and in so doing had developed abnormally and formed certain faulty habits of action. The cleft palate operation therefore should be done as early in life as possible, before these habits of faulty speech are formed. Even then we do not obtain good speech because under the most favorable circumstances and with the most skilful operation we do not secure a palate of suitable dimensions and normal functional activity. Nature as a rule has failed to give us sufficient tissue here and some of it must be sacrificed in our efforts to unite the parts, and the muscular control of the palate after the operation is always very deficient.

The velum palati, that portion of the palate which is so essential to good speech, is too short. There is not enough material to make a veil sufficient to close what I have called the palato-pharyngeal chink, and the result is that the sounding breath which should be directed through the oral cavity in the articulation of many sounds, is allowed to pass up through the nasal cavities instead, and this deflection makes the utterance of certain consonant sounds quite impossible.

Training will improve this condition to some extent but not very much unless at the same time we are able to increase the effectiveness of the soft palate and uvula. The palate is too short and tense. It is stretched across midway between the tongue and pharyngeal wall and held down by the palato-glossi muscles, which are also too short. In addition to this the pillars of the palate are usually bound together by old tonsillar adhesions, which assist in preventing the normal action of the palate. The uvula is either absent altogether or very deficient in size and useless so far as its natural functions are concerned. The indications here have been to secure greater freedom in the movements of the palate and for this purpose I have separated the adhesions between the pillars and divided some of the fibers of the palato-glossi muscles, and then by frequent stretching of the parts and massage with the finger placed in the mouth, I have been able to give him a more useful palate and his speech is already quite intelligible, although we have only nicely begun his training and these other methods for the

improvement of speech. My next step will probably be to divide some of the fibers of the palato-pharyngeal muscles. His speech is far better now, I think, than that which we could have secured with an artificial obturator and it is always a pity I think to put an obturator in the mouth of a boy of this age.

The next case is the only one of its kind so far as I know. This young man is 15 years of age, born in this city of American parentage, and is next to the youngest of five children, the other four being strong and healthy, although two of them are said to have had some slight derangement of speech in childhood from which they recovered without special treatment. The family physician informs me that the mother had frequent uterine hemorrhages during the time she was carrying this child, and after delivery both mother and child were very weak and anemic. The child's heart action was feeble and the foramen ovale was late in closing. He was what is known as a blue baby and had occasional spells of what was called suspended breathing. At the age of 1 year he had a severe attack of broncho-pneumonia, from which he recovered slowly, and he was extremely delicate until the age of 7 years, since which time he has been in fairly good health. His speech developed very slowly and imperfectly and he was brought to my clinic about the first of the present year. He could talk glibly, but not a single word was at all intelligible. I asked him his name and address and he said "Tháhti Thóu, púrti thab tháti páthi," meaning Alfred Lawrence, 3918 Parrish. I asked him to say the days of the week and he said "Túrdi, Tháhdi, Túdi, Thádi, Bódi, Báhdi, Táhdidā."

We found that he had been attending school regularly, where he had easily kept abreast of his mates in his studies and shown himself to be rather above the average in intelligence. This is very unusual. In fact I know of no other case with such a history. Even though the brain be in perfect physical condition and the defective speech be due entirely to imperfections in the peripheral organs, cerebral action is usually very much impaired.

In a case which I reported two years ago the mental growth was checked to such an extent as to actually suggest idiocy, but just as soon as we opened up the avenues for oral expression his mentality increased with most wonderful rapidity.

Usually defective speech is a great hindrance to mental development and this is especially true as the patient gradually merges into adult life. It is then that he begins to feel the need of effective speech, and unless he can exchange with his fellows the products of the mind these products will soon cease to materialize. This boy has gotten along very well up to this point. He is almost ready for the high school, but I believe he had about reached his limit of normal mental development and the next few years would have witnessed a retrograde action. Even now he has a kind of hang-dog expression as if he were sorry that he is living, but that is not so marked as it was four months ago and it would have increased enormously in the next few years, for his defect was beginning to weigh heavily upon his mind.

Now, what was the cause of this defective speech? Peripherally there were no structural irregularities in the organs except some bad incisor teeth and a slight enlargement of the faucial tonsils with some adhesions between the pillars, which I removed, although they could have but little bearing upon the trouble.

There was really nothing in his mental or physical condition to account for his defect and therefore I think we must conclude that the cause probably began in intra-uterine life and existed all through the formative speech period up until about the seventh year. Before birth the blood which should have gone to nourish the fetus passed off in frequent hemorrhages, and for several years after birth the child's own circulatory apparatus was entirely inadequate, and as a result of this faulty circulation and anemic condition all the mental and physical processes were greatly retarded and speech being one of the most complicated of these processes suffered most and improved least with his improvement in general health. A careful study and analysis of the action of the peripheral organs during his attempts at speech revealed the fact that only the simplest movements and combinations of these organs were made. The anterior stop positions alone were used, that is, the one between the lips and the one between the tip of the tongue and the teeth, or what remained of three very bad teeth, in front. The consonant sounds which he used were, of the labials p, b, m, of the linguo-dentals, th as in thou, and of the linguo-palatals t, d, n and occasionally l and r in the middle of a word. The voiced th was his favorite sound for the beginning of words, and the voiceless th (as in thin) he did not use at all, but changed it to p. For instance, he would say "pirty" for thirty.

I will now describe some of our methods of treatment and their results. Our task was not so much to develop the speech center I think, but rather to train the motor track and the various peripheral muscles and organs of speech into right action.

The center for word concepts was intact, as was the motor track supplying the muscles of the arm for writing; for he did his thinking in the words that he uses now and he wrote a good hand and spelled very well indeed.

We began with exercises to develop the various muscles of the lips, the tongue and the palate. He could not even open his mouth properly and it was some days before we could get a satisfactory view of his tongue and palate. In trying to open his mouth the orbicularis oris would close sphincter-like and he could not relax it, and I am convinced that he never knew what it was to smile. Various exercises were given him to correct these faulty muscular actions and he was carefully shown day after day how to make the elementary sounds of the language, where to place the tongue, how to shape the lips, etc., etc., much after the manner that we teach deaf mutes to speak, and we have found that there are no sounds that he can not master, and I may say that he has not mastered, although he needs further practice to acquire greater facility of speech.

In conjunction with this case I present a somewhat similar one, although they differ in some important points. This boy comes from Virginia and is 10 years old. His trouble is simply that of arrested speech development, such as we very commonly meet with in children. His speech not only did not improve but it was actually deteriorating. There is the history of a fall at the age of 7 months, in which he received a severe injury to the nose, although there appear to be no special external evidences of such injury. There is no intra-nasal pressure and there are no oral or pharyngeal lesions of any kind to account for the trouble. He has had measles, whoop-

ing cough and malaria of a very severe type, and he had convulsions when teething. His father and mother are second cousins and still living. His grandfathers were first cousins and both died at the age of 45 years. There was consumption in both families and a history of various kinds of nervous affections and backward speech in many of the children. The mother of this child had defective speech and her brother had some form of paralysis and used to stammer at times, and died at the age of 38.

And so this boy springs from a race of defectives, and as is the history of so many of these cases, the tendency toward defective speech seems to be inherited. His defect may be characterized as the mutilation of words with what Mr. S. S. Buckman has called decapitation and decaudation. He cuts off nearly all the initial consonants. For moon he says "oon," for Sunday he says "unday," for cat he says "at." And there is also some decaudation or the cutting off of the final consonant; as for chair he says "a," for three he says "e," for four he says "o."

The treatment of these two cases has been along the lines of physiologic principles. The various organs of speech, viz., the lips, tongue and palate, have been trained to take the proper positions for the articulation of each sound, and as these positions are constantly changing and interchanging, this is no easy task; and yet the results in these cases have been immediate and most satisfactory.

The speech of neither of these boys was at all intelligible and that of the first one did not even resemble or approach the normal, while the speech of the second was mutilated, decapitated and decaudated.

The first boy has been under treatment about four months and the younger boy came to my clinic April 6. The first boy can now read and speak very well and can articulate very clearly any word with which he is at all familiar. The second boy can enunciate perfectly a long list of words which he has learned. These are both dispensary cases and have not received the regular and systematic treatment which they might otherwise have had. I would say further in reference to the treatment of all these cases that careful attention has been given to the proper methods of breathing, and they all breathe alike and in a certain definite manner. This is most important in the treatment of stammering.

NOTE.—In addition to the above three cases, Dr. Makuen exhibited three cases of stammering, in two of which the defect had been entirely eradicated and the third was in process of treatment. Methods of breathing, etc., were freely demonstrated.

DISCUSSION.

Dr. VANSANT.—It is perhaps proper to exclude the psychic causes of speech and consider for a moment the effect on speech of the various abnormalities of the throat and nose. The recognition of such local conditions and their removal in early life seems very important. We are familiar with the thick speech in cases of nasal obstruction, and I have noticed a want of co-ordination between thought and speech in patients suffering from these local lesions. A man with hypertrophy and enlarged glands about the throat may think one word and speak another. That being the case, a certain defect of speech naturally arises. He becomes embarrassed, seeks for the word he is thinking of, and stammers. We know how young children, who want some object whose name is unfamiliar, will stammer before bringing out the word. Elocution is simply for the purpose of voice culture. I think it is a mistake to send a stammerer to an elocutionist before a careful examination of the nose and throat has been made. Remove the abnormal conditions and afterward employ proper teaching to improve the speech. Many methods are pursued by teachers for the cure of stammering. Dr. Makuen's brings under

more perfect control the various muscles used in the production of voice.

Dr. SCHEPPEGRELL—I will ask Dr. Makuen whether he ever heard of the method of a man who traveled over the country a few years ago and made a great deal of money. After insuring his fee, he gave only the direction, "lower your voice." For instance, if the patient used his throat register, he was told to use his chest register. The result really seemed to be to stop the stammering, but I do not know anything as to the permanent result of the treatment.

Dr. DELAVAN—In no subject has there been so much quackery and deception as in the cure of stammering. For a man to take up the matter in a scientific, broad-minded and humane way, as Dr. Makuen has done, is quite rare. The mass of literature on the subject does not give a single practical idea. Attention should be given first to the proper management of the breath and the organs of articulation, the proper development of the physical state of the patient, and the careful study of the throat and the removal of any local pathologic defects, adenoid tissue, etc.

Dr. RICHARDS—In the manufacturing community in which I live I find many speech defects among the children. The mothers work in the mills too long previous to the birth of the children and the children themselves are put into the mills very young. These defects are often associated with deficient intelligence, but I have one patient who aside from this trouble is a fairly bright child. The boy can not protrude his tongue and can pronounce no word except his own name, "Elmer," which he can speak intelligibly. At the Massachusetts General Hospital the trouble was regarded as central in origin. There is certainly some hypoglossal paralysis. I would like to know what Dr. Makuen would suggest in a case of this kind.

Dr. COHEN—In the training of the muscles of the palate the great difficulty is that the soft palate can not occlude the pharynx, and thus it is very rare to see much improvement in speech after operation. For this reason many advisers prefer some artificial appliance. If you ask a patient to choose between an imperfect throat and imperfect speech, he will usually want his speech restored at almost any cost. It is a very great achievement to get as good results as shown in the first case. The great difficulty in operation is that we have to shorten an already short palate. In 1874 (see Transactions AMERICAN MEDICAL ASSOCIATION, 1874) I devised an operation for cleft palate, in a girl of 15. I simply split the edges on each side and spread them out, uniting the two halves. This is the only case where I have seen good speech after operation. I have never performed an operation for cleft palate since, but have invariably advised obturators, and with excellent results. A surgeon once brought me a case on which he had operated for cleft palate, with good results, and he was about to take away the enlarged tonsils. I advised against this procedure, because these tonsils occluded the pharynx and aided speech and their removal would have reproduced the imperfections in speech.

Dr. WOOLEN—I would ask whether there is a method of securing adhesion of the two sides of the uvula. In a case I have, strong adhesions of the soft palate were secured, but a bifid uvula remained. Speech has been wonderfully improved, which I think is largely due to the elocutionist to whom I sent the patient after operation, but there are still certain defects in her speech.

Dr. COHEN—You can get union by putting a drop of nitric acid in the apex of the cleft, and when that spot has united, putting on another drop just below it, and soon.

Dr. MAKUEN—The average elocutionist does not know what to do with these cases. He has no idea of the proper method of breathing, which is the first thing that has to be taught. I have some assistants in my clinic who understand this subject very well. My elocution teacher in school taught me a method which was entirely wrong. Elocutionists are mainly skilled in teaching the refinements of speech to those who can already speak fairly well. The defective must be shown how to place and use the tongue, lips and palate and the respiratory and buccal muscles, and must be drilled into it. In regard to the various tricks for the cure of stammering, I am sure that I have heard of 500 of them. Few of those who treat stammering will tell you the method used. Dr. Richards mentioned a case of his, a boy who can not protrude his tongue properly. The case I have shown you from Wilmington was one of that kind. The cutting of the anterior fibers of the genio-hyo-glossus muscle relieved him. The operation seems to loosen up the tongue so that the patient can be taught to speak. With reference to the mental condition in these cases, Dr. Daniel G. Brinton says that the genio-hyo-glossus muscle is supposed to have some special connection with the brain, and those who have defective tongue muscles are likely to have a defective brain. I had a

case which had been given up as idiotic. I did this operation and the boy is now one of the brightest in his school. It is better to operate under general anesthesia. In stammerers quite a large percentage have bifid uvula.

CHRONIC STENOSIS OF THE LARYNX WITH FIVE ILLUSTRATIVE CASES.

Presented to the Section on Laryngology and Otology, at the Forty-eighth Annual Meeting of the American Medical Association held at Philadelphia, Pa., June 1-4, 1897.

BY WILLIAM S. JONES, M.D.

CLINICAL PROFESSOR OF LARYNGOLOGY IN THE JEFFERSON
MEDICAL COLLEGE HOSPITAL.
CAMDEN, N. J.

I reported a case of prolapse of the laryngeal ventricle in the *Medical News*, Feb. 2, 1895, which presented at intervals marked symptoms of stenosis, the dyspnea at such times being very severe. Since that time, a number of cases of chronic stenosis, due to different causes, have come under my care, and I hope that a short history of some of these may prove both interesting and instructive.

Any cause acting either from within or from without which lessens the lumen of the larynx, will produce the symptoms of stricture, and so long as the cause is active there will be actual constriction. The condition may be acute or chronic, according to the length of time the process has been present and active, but the ultimate symptoms of the two varieties are the same, and the gravity of the symptoms is always dependent upon the severity of the lesion and the extent to which function is interfered with.

The symptomatology is characteristic. Dyspnea is always the most urgent symptom but there may also be present dysphonia, dysphagia, pain, cyanosis from improper aeration of the blood, forced respiration bringing into action the accessory respiratory muscles, anxiety of countenance, engorgement of the venous system and increased breath-sounds in the larynx. In the chronic cases, probably the most frequent initial symptom is dysphonia or hoarseness, which is sooner or later followed by the other characteristic signs.

Case 1.—R. S., aged 35 years, while attending a ball game three years ago, cheered very loudly the success of his favorites. He at once experienced a hoarseness which, however, lasted but a few minutes, and no further attention was given the condition. Two weeks later, hoarseness again developed and gradually increased in severity. After this condition had progressed several weeks, he began to have interference with the breathing which was at times very marked. Four months after the first onset I saw him and found a large mass, of light red color, situated just above the left vocal band and resting upon it. The history of the violent straining of the larynx at the ball game, the immediate hoarseness, probably due to a local congestion, the gradual onset of dysphonia and dyspnea were, in part, characteristic of a prolapsed ventricle, and the appearance of the mass confirmed the diagnosis.

We would state that the diagnosis is by no means easy, and but a very few cases have been reported. The color and smooth surface excluded angioma and papilloma, and the sessile attachment was against myxoma. Its position, shape, color and the absence of surrounding inflammation or infiltration excluded a malignant or tuberculous lesion.

Replacement of the prolapse was performed several times but it returned as soon as pressure was removed, so I resorted to the galvano-cautery to accomplish complete removal. The knife used had a shield to protect the ventricular band. At each visit several applications were made with the knife at a dull-red heat, and after the application of a 20 per cent. solution of

cocain. The parts healed nicely after complete removal was effected and there are now no appreciable symptoms indicative of any trouble having existed in his larynx. The parts are normal in appearance.

While this case might not be considered one of true stenosis because of the absence of new growth or constricting tissue, it seems to be proper to classify it as such because of the presence of the characteristic symptoms of that condition.

Case 2.—Mr. H. H. A., aged 52 years. The patient was first seen in September, 1896, and the following facts were elicited: The family history and the patient's early record are very good, there being no tuberculous or other constitutional disease present. He has always had good health, the only sickness having been an indefinite venereal trouble thirty years ago from which, however, he quickly recovered. During all these years, he has been engaged in hard labor and exposed to all kinds of weather. He refers the beginning of his present trouble to a bad cold contracted in August, 1895. Dyspnea began in September, 1896, and grew steadily worse until October 12. I first saw him early in September. At that time he had slight hoarseness, and examination showed a small mass, the color of the normal larynx, beneath the left vocal cord. He was placed upon specific treatment tentatively. He grew steadily worse. Marked dyspnea developed and almost complete aphonia, and all the usual symptoms of advanced stenosis. October 12, examination of the larynx showed marked thickening of the left ventricular band and bulging of the left cord, caused apparently by a swelling back of it. The swelling was so great that breathing was almost impossible. The right side was normal. Tracheotomy was performed at once.

The operation was done under eucaïn anesthesia and the third, fourth and fifth rings cut. Three days after the operation he contracted an acute bronchitis, which however subsided in a few weeks and he left the hospital at the end of a month. One month later he began to breathe through the mouth, also to speak, and in two months his voice was perfectly normal and his breathing free. He still wears his tube but keeps it plugged all the time.

The cause of the stenosis in this case was obscure. There was no ulceration and no pulmonary involvement, which, together with his recovery without medication, exclude tubercular laryngitis, and syphilis was excluded by the week's trial treatment. The probable cause was a localized chondritis which subsided after the irritation by breathing, coughing and talking was removed. This also seems probable from the fact that at present the larynx is normal in every respect.

Case 3.—W. W., aged 42 years. His family history is negative excepting that one brother died at the age of 21 of acute miliary tuberculosis. His personal history reveals that he had three chancroids (so-called) in 1872, which were about three months in healing. He, however, never saw any secondary symptoms of syphilis, but as he is colored they may have been present and unnoticed. In 1891, he was kicked by a horse in the right side of the face. The malar and superior maxillary bones were fractured, and a portion of the latter was removed by the surgeon in attendance. About three weeks after this injury, according to his statement, a sore throat developed and has continued more or less ever since. In 1893, an abscess formed in the left side of his neck and was opened. This probably came from broken down cervical glands, as a number of them in that region are still enlarged. About the middle of July, 1896, he began to have dyspnea and difficulty in swallowing solid foods, with occasional attacks of vomiting. These symptoms gradually increased until the middle of October when I saw him. For a week previous to this time dyspnea was very marked, and he had some pain in both tonsillar regions.

October 25, I performed tracheotomy under eucaïn anesthesia. He made a slow recovery from the operation, having much inflammatory reaction about the wound. He was given 1.3 grams of potassium iodid three times a day immediately after the operation, and this has been kept up until the present time. The condition of the larynx remained unchanged for four months in spite of the administration of the iodid, but then the obstruction began to disappear and at present (May 1) his larynx is almost normal and his voice is completely restored.

This case was undoubtedly one of syphilis of the larynx and the favorable result is due in part to the early operation, removing a fertile source of irritation by turning the current of air aside and preventing coughing, and in part to the steady use of the iodid before the new tissue was thoroughly organized, as were organization complete, a contracting stricture would undoubtedly have resulted.

Case 4.—P. B., aged 53 years. His family history was very good, also his personal history, he having had no sickness except the grip three years ago. His present trouble began about Sept. 1, 1896, with slight dyspnea which gradually increased, but he continued his work as a laborer until October 8. As his difficulty of breathing became more severe he developed a cough, but had no pain or difficulty in swallowing. He lost flesh rapidly during this time. He first came to the clinic October 27 and an examination then revealed a growth involving the right side of the larynx and pushing the vocal band to and beyond the middle line. The diagnosis of carcinoma was made and immediate tracheotomy advised, with a probable resort to laryngectomy later. The first operation was done the next day under eucaïn anesthesia. He recovered quickly from the operation but continued to lose flesh. The laryngeal swelling subsided somewhat after the operation but the growth increased steadily in size. He refused laryngectomy and went to his home in a neighboring city, where he is still living, but in the last stages of malignant disease.

Case 5.—W. C., aged 30 years, a laborer. Nov. 12, 1896, in a fit of despondency, he attempted suicide by making a large cut in his throat with a penknife. He penetrated the trachea about the second or third ring, twisted the blade about and cut up and down for an inch or more. He was taken to a hospital, where the wound was dressed but not closed, nor was there a tube inserted. One week later, it was noticed that he could not breathe through the mouth when the wound was closed by pressure. It was deemed necessary to introduce a tracheotomy tube, an anesthetic was given him, a tube inserted and the wound stitched around it. Two weeks later, the surgeon attempted to pass a tube through the trachea and larynx from the tracheal wound but did not succeed, the part being shut off. He was then sent home to allow the wound to heal before further operative interference was instituted. Nothing further, however, was done and he was sent to me. The condition of his larynx at present is as follows: The right side is drawn slightly downward, the right vocal band is in the median line and immovable, being fixed by scar tissue beneath it; the left side is normal in situation, the cord is freely movable and can be brought to the middle line perfectly. The entire left side is free for three-fourths of an inch below the vocal band, while the right side has a band of cicatricial tissue just below the cord, which extends downward for three-fourths of an inch and then spreads out to the other sides, completely occluding the trachea. The surface of this membrane is smooth and the lowest point is near the center. From below, the trachea is entirely closed above the tube and the cicatrix is about one-half an inch in thickness.

I have made no attempt at opening the trachea but think it can be done comparatively easily from above. The method of procedure will be to make an incision through the scar tissue with a long knife and enlarge this opening by graduated bougies until the entire lumen is established, and then keep it open by a tube attached to the one now in the tracheal wound until the surrounding parts are healed. He might even always wear an intratracheal tube, as it is too low to interfere with his voice, yet will insure an open passage for air.

201 Broadway.

SOCIETY PROCEEDINGS.

New York Academy of Medicine—Section in
Orthopedic Surgery.

Meeting of December 17, 1897.

Dr. A. M. PHELPS read a paper entitled:

A CONSIDERATION OF SOME OF THE PATHOLOGIC AND MECHANICAL
PROBLEMS OF HIP DISEASE.

He presented the view that nature attempted to repair the lesion producing hip disease by inflammatory action which was a normal process of repair until the inoculation of germ life which marked the beginning of disease in the area of inflammation. The absence of inoculation gave rise to the ephem-

eral cases of hip disease which rapidly recovered without deformity or disability, but inoculation gave rise to the ordinary type of the disease. If the phagocytes were weakened by the strumous condition of the patient, they failed to destroy the germs. If, however, germ life was destroyed, repair went on and the parts were restored to their normal condition. Cavities and foci produced in the course of hip disease by the slow growth of the bacilli of tuberculosis might be inoculated by the rapidly growing pyogenic cocci when a hot and possibly painful abscess appeared and called for the knife and drainage. The adduction, flexion and inward rotation attending the third stage found a mechanical explanation in the fact that when the limb passed twenty-five degrees of flexion the adductors became internal rotators, the external rotators became abductors and the tensor vaginae femoris became a powerful inward rotator. In the application of mechanical treatment it should be remembered that the powerful groups of muscles acting upon the thigh did not act on an axis with the shaft but nearly on a line parallel with the axis of the neck of the femur. Lateral traction, therefore, should be made in the line of the axis of the femoral neck and not of the shaft.

Dr. G. R. ELLIOTT said that in hip disease we had a depraved process. The whole system was at a low ebb that tended to favor the development of the disease. He thought that this condition of inactivity required the use of some form of apparatus which did not, as all the instruments now in use did, subject every part of the child's body to great expense for the sake of the hip. The ideal splint of the future would not lock up so much of the body by apparatus but would fix only the diseased joint.

Dr. R. H. SAYRE advocated the use of traction to fix the joint, give it physiologic rest and relieve the pressure to which the diseased bone was subjected. He thought that it was difficult to apply lateral traction by a splint, but in bed, lateral traction was easily applied and added to the patient's comfort. In children, however, in whom the neck was nearer in line with the shaft of the femur than in the adult, he believed that longitudinal traction was sufficient. He thought it well to apply massage to overcome the muscular atrophy of disease, but it took a great deal of care to limit the application to the sound part and not interfere with the inflamed joint.

Dr. T. H. MANLEY held that all pus accumulations about a joint should be evacuated early and thoroughly. He asked Dr. Phelps's opinion of the intra-articular injection of solutions of iodoform.

Dr. PHELPS said that filling a joint with an insoluble compound did more harm than good. If he found a joint in which there was fluid, he evacuated it.

Dr. A. B. JUDSON said that the destruction of the head and acetabulum was often cited as an evidence of the bad effects of muscular contraction and of the necessity of making traction. He thought that this destruction was rather an evidence of the bad effects of the pressure made by the weight of the body, as patients with hip disease, if unmolested, were in all except the most advanced stages on their feet as much as well children. He believed that traction was the best method of promoting fixation and in painful stages it was indispensable, but that removing the weight of the body from the joint was also an indispensable part of the treatment and useful through far longer periods than traction.

Dr. T. H. MYERS had made a careful study of the ephemeral cases and believed that the lesion, of whatever nature it might be, was in the bone itself. He would make a distinction between these cases and rheumatic, gonorrheal or other affections of the joint cavity and ligaments. He could not recall any acute case of hip disease which had not been relieved by longitudinal traction alone.

Dr. R. WHITMAN said that the breaking down of bone appeared to be the effect of a destructive process, aggravated by the friction of the diseased surfaces upon one another, by the weight and strain of use in the attitudes of deformity and by the muscular spasm which forced the diseased parts together. The intensity of the spasm was in inverse proportion to the fixation and rest that could be assured. When the patient was recumbent the most important means of fixing the joint was traction. The ambulatory brace should remove the weight of the body from the weakened part, but it was so ineffective in fixation that its use should be combined with splinting of the joint. He had always insisted that the hip should be slightly abducted.

Dr. PHELPS said that abduction should be avoided. It was one of the difficult conditions to correct in the first and second stages.

Dr. JUDSON said that in recovery with ankylosis abduction was desirable. It gave a factitious length to a limb which was

probably really shortened, and saved the use of a high sole or reduced its height.

Dr. SAYRE thought that the limb should be in as nearly normal position as possible, neither abducted nor adducted.

Dr. H. L. TAYLOR thought that about five degrees of abduction would compensate for some of the shortening and make the limb more useful.

Dr. PHELPS said that ankylosis was due to the severity of the inflammation, the character of the disease, the destruction of bone and contraction of cicatricial tissue about the joint. It was prevented by the use of an apparatus which seized the pelvis and fixed the joint from the commencement of the treatment until the patient was cured. The joint being thus held at perfect rest, nature went on in her effort to cure, uninterrupted by the trauma of motion. The splint was not used to overcome deformity, but merely to hold the limb in a perfectly straight position after the deformity was corrected by bed treatment.

Meeting of January 21, 1898.

CONGENITAL ABSENCE OF PECTORAL MUSCLE.

Dr. TAYLOR presented a patient who had been brought to him because of asymmetry of the upper part of the chest in front. The patient was a boy six weeks old. There was normal fullness of the right side, while the left side where the pectoralis major should have been was much depressed. This was the fifth child of the mother, the others being healthy. Labor was normal. The child moved both arms equally well.

Dr. WHITMAN presented a boy 16 years old with a similar condition. When five years old he had pigeon-breast. On account of round shoulders and projecting scapulae he had been brought to Dr. Whitman, who had found a defect of the right pectoralis major due, apparently, to congenital malformation from which the boy had suffered but little inconvenience although he was left-handed. The muscular deficiency had never been recognized. The clavicular part of the muscle was normal, but the sternal part was represented simply by a fold of fibrous tissue which could be brought into prominence by certain motions of the arm. He had considered the possibility of poliomyelitis as a cause, but after seeing Dr. Taylor's patient, he thought the trouble was due to congenital malformation. He had seen a somewhat similar case in which absence of the right pectoral muscle had been accompanied by defective ribs, slight lateral curvature and webbed fingers.

Dr. MYERS had the day before seen a patient affected with wry-neck from general shortening of the muscles of the right side. There was also on both sides a very marked depression between the inner border of the deltoid and outer border of the pectoralis major, apparently due to absence or defect of the clavicular part of the large pectoral muscle.

Dr. SAYRE said that in a boy who had been brought to him for pigeon-breast he had found the scapulae very prominent and an almost complete absence of the right pectoralis major. The disability was not serious. He had referred the condition to an attack of poliomyelitis at the age of three, of which he had obtained what seemed to be a creditable history. The case might have been, however, an instance of congenital defect of the muscle.

Dr. ELLIOTT did not think that it was possible to exclude poliomyelitis in either of the patients shown. He had seen patients in whom a muscular defect in other parts of the body, at first thought to be congenital, had been found to be the result of poliomyelitis. He thought cases were not uncommon in which the effects of the disease were limited to a single muscle or even to a part of a muscle.

Dr. TAYLOR said that in the case of the baby it would be necessary to assume that the disease had been *in utero* as the condition of the muscle had been present from birth and the atrophy was so complete that it suggested the absence of development rather than paralysis. If there had been paralysis it must have been at the very beginning of the development of the muscle since paralyzed muscles retained their fullness for a considerable time.

DEFORMITIES FOLLOWING TYPHOID FEVER.

Dr. W. R. TOWNSEND presented a male 19 years of age who had complained of spinal pain and stiffness since recovery from typhoid fever last February. The vertebral column was very rigid with a slight curve toward the right in the lower dorsal region and a posterior curve of the lower dorsal and the entire lumbar region. There were also a number of swellings distinctly connected with the bone in different parts of the body resembling cold abscesses of tubercular subjects and syphilitic nodes. They were not very soft and there was no fluctuation. The general health had been poor since the fever. Parsons of Johns Hopkins University, had described such swellings as

appearing several months after typhoid fever. He had found in them the typhoid bacillus, the staphylococcus and the bacillus coli communis and had advocated total extirpation of these foci.

Dr. SAYRE thought the boy might be suffering from hereditary syphilis which had first made its appearance when his health was broken down by the attack of typhoid fever. If local treatment was necessary the foci might be incised and scraped and packed from the bottom. As the epiphysis is involved in several instances enucleation would endanger the usefulness of the joints. He called attention to the girdle-mark, which is a pathognomonic sign of disease of the spine and advised treatment as of an ordinary case of tuberculous disease of the spine.

Dr. V. P. GIBNEY advised that a trial of antisiphilitic treatment be followed by general constitutional treatment, the administration of cod-liver oil, etc. He could see no advantage likely to follow cutting out the foci. Spinal rigidity after typhoid fever was due to a mild periostitis about the points of exit of the nerves. He thought forcible correction with anesthesia would be excellent treatment in this case. He had seen a number of typhoid hips. One of them was under treatment by repeated forcible motion under anesthesia followed by massage.

Dr. WHITMAN thought that the spinal deformity was the most important feature of the case and that it required immediate correction. He said that the girdle-wrinkle was not caused by muscular spasm but was simply a fold in the abdominal wall answering to the projection backward which had taken the place of the normal lumbar lordosis.

Dr. SAYRE said that he had noticed the girdle-wrinkle in many cases. It would be higher or lower according to the location of the disease. It was due to muscular spasm which accompanied any muscle subject to irritation and joint inflammation. It was diagnostic of Pott's disease and was present even when there was no appreciable projection.

Dr. TOWNSEND said taking the foci out would, in nearly every instance in the patient in question, involve opening into a neighboring joint. He would put the patient on antisiphilitic treatment and later consider the other suggestions made.

Chicago Ophthalmological and Otological Society.

Regular meeting held Jan. 11, 1898, in the Stewart Building.

Dr. MONTGOMERY in the chair.

There were eighteen members and visitors in attendance.

The minutes of the previous meeting were read and approved.

Dr. W. F. Coleman was elected president; Dr. H. M. Starkey, vice-president; Dr. C. P. Pinckard, secretary, and Drs. Hotz, Montgomery and Wilder the Committee on Membership for the ensuing year.

The treasurer's report was read and adopted.

Dr. WOOD reported a case of

PRIMARY SARCOMA OF THE LID.

Baby A., aged 7 months, an only child, was born a healthy and well-developed infant, and although nursed on the bottle has always been vigorous and to all appearances free from any hereditary disease. There is no history of malignant neoplasms affecting immediate ancestors. When she was 6 weeks old the mother noticed a slight elevation on the right upper lid. It was firm to the touch, rolled about under the finger, and was not surrounded by a red or swollen area, on the skin surface, at least. On consulting an oculist in the neighborhood, he advised her to watch the little tumor, and if it increased in size it might be safely removed later on. It remained *statu quo* until the child was 3 months old, and then the mother believed it to be growing and consulted a well-known ophthalmologist in Boston. He would not give a positive opinion, but kept the patient under observation for about a month longer before advising its immediate removal. As the family was about to remove to Chicago, nothing was done. The condition of affairs was about this when I first saw her, two months ago: The right upper lid is slightly swollen throughout and of a darker pink than the corresponding left lid: there is a rounded prominence occupying the junction of the middle and inner third of the lid. On palpation an irregular oval, apparently movable body of rather firm consistence and of the size of a white bean is felt, not unlike the ordinary chalazion. The dermal vessels are slightly more numerous and larger than are those of the opposite side. On everting the lid the body seems to project somewhat on the conjunctival aspect of the lid, and corresponding to the projection is a round

mass covered with red and thickened mucoea. The vascular supply is decidedly greater than in the ordinary non-suppurating chalazion. The mass appeared to involve the tarsus. There is apparently no pain in the eye and no increased conjunctival secretion.

The tumor was removed completely, under chloroform narcosis, from the conjunctival surface, using a fenestrated forceps. There was free hemorrhage and the tumor appeared to be imperfectly encapsulated. It involved the tarsus, part of which was removed at the time of operation. Macroscopically it resembled a small piece of muscular tissue. Dr. Evans of the Columbia Medical Laboratory, examined the growth and gives the following report: "Fresh specimen, 6x4x2 mm. No epithelial covering. Microscope shows it to be composed of round and spindle cells, more of former, with considerable intercellular substance, some pre-existing fibrous tissue, an artery with unusually thick walls. The growth is sarcoma."

The sections exhibited showed as naked vessels communicating directly with the cells. So far there has been no recurrence of the growth.

In reply to Dr. Pinckard, Dr. WOOD stated that the clinical diagnosis rested on the question of the injection both of the conjunctiva and the skin, it being more marked than in an ordinary chalazion.

Dr. ALLPORT showed a case of

TUMOR OF THE FUNDUS,

suspected to be a beginning leucosarcoma of the choroid. The patient a woman 28 years of age, with a vision of 20-20 in each eye. On the right side she has ophthalmic goiter with classic symptoms, the fundus of the eye being normal except for the enlarged veins. In the left eye a small round grayish white elevation, just to the macular side of the disc, which it apparently joins. The tumor is about half the size of a nerve head and looks like a mass of clouds, the elevation being about 1 D. A retinal vessel courses over the surface and some pigment on the surface would seem to indicate that it originated in the choroid. Forming a semicircle around it may be seen many pigmented choroidal splashes. The peripheral field for white is perfect, but a small scotoma for red and green close to the physiologic blind spot was found.

Dr. HENRY GRADLE reported a case of

TARSITIS

and reviewed the literature. There are on record only twenty cases of this rare affection, but from the similarity of all a well defined type of disease results. The affection is always of syphilitic origin. Four cases with acute onset are reported as early manifestations, while all the others presented a chronic course and occurred late after the infection. It appears in the form of a diffuse, hard swelling of the tarsal plate of the lid. With two exceptions it was limited always to one lid of one side. There is neither pain nor tenderness. As a rule, the skin is not altered; in some instances it is described as livid. In the speaker's case there was intense inflammatory congestion and edema of the skin of the upper lid as long as the case remained under observation. The conjunctiva is generally not involved. In some instances, like the present one, there was catarrhal conjunctivitis with some hypertrophy. In the present case a high grade of congestion and chemosis was observed in the ocular conjunctiva, and the cornea was temporarily clouded. In all cases on record the disease was controlled by specific treatment, but invariably lasted months, several times a number of months. In the speaker's case the patient, a girl of 24 years, did not admit or present evidences of syphilis, but was put first upon mixed treatment, subsequently upon large doses of iodid of potasium without any visible influence. Swelling increased during the observation in spite of the treatment. The accompanying catarrhal conjunctivitis was temporarily aggravated by the patient's improper use of the bandage, but healed on proper management and the use of nitrate of silver applications. This, however, did not lessen the tarsal swelling and influenced but little the inflammatory edema of the skin. A decided control over the tarsal swelling was finally obtained by an ointment of 10 per cent. of pyrogallie acid. The influence of this salve was studied advantageously on account of several interruptions in the treatment with a standstill of the tarsal swelling. The patient was lost from observation before a complete cure was obtained.

Dr. STARKEY said: This case is the only one of the kind I have ever seen. I ascribed the same cause as did Dr. Gradle, and gave her the mixed treatment in moderately full doses, but did not check the inflammatory condition at all.

Dr. ROBERTSON of Davenport, Iowa, showed

A POST-ORBITAL TUMOR

taken from a boy about 10 years of age, in whom exophthalmus

of the right eye had existed for two years, it being so marked that the lids could not cover the cornea. The resistance was so great that the diagnosis of solid tumor was made. The motion of the globe was *nil*, as also the visual power. Immediate removal was done, and specimen shows that the tumor originated in the optic nerve some little distance behind the eyeball as there is apparently healthy looking nerve between the tumor and the eyeball. It was attached to the periosteum just external to the edge of the optic foramen. The tumor was removed in August, 1896, and since that time the boy has been wearing an artificial eye with no return.

In reply to Dr. Pinckard, Dr. Robertson said that there was no evidence inside of the eyeball except for atrophy of the optic nerve fibers.

Dr. ROBERTSON showed some Texas screw worms removed from the brain of a man postmortem, they having entered through the nose and pierced the ethmoidal plate.

On motion, the Society adjourned.

C. P. PINCKARD, Secretary.

Chicago Gynecological Society.

A regular meeting was held Feb. 18, 1898, in the Stewart Building, with the President, Dr. HENRY P. NEWMAN in the Chair.

The Society entertained the Trustees of the AMERICAN MEDICAL ASSOCIATION. The guests of honor were Drs. Alonzo Garcelon, G. C. Savage, J. N. Love, E. E. Montgomery, J. M. Mathews, C. A. L. Reed, Joseph Eastman, J. T. Priestley, Truman W. Miller and John B. Hamilton.

Dr. FRANKLIN H. MARTIN exhibited two specimens of fibroid tumor of the uterus removed by hysterectomy. The specimens showed how difficult it would be to apply myomectomy to all cases. He thought it would be impossible to have removed these growths without, at the same time, removing the uterus.

Dr. J. FRANK exhibited specimens of dermoid cyst which he brought with him from Vienna when abroad last summer.

President NEWMAN extended a cordial invitation to those whose names did not appear upon the program as essayists to participate in the discussion.

Dr. JOSEPH EASTMAN of Indianapolis, Ind., then read a paper entitled

VAGINAL HYSTERECTOMY AND IGNI-EXTIRPATION.

The essayist said that the Eastman method for vaginal hysterectomy as devised and followed by him for ten years, was described as long ago as 1890, and its advantages over many other methods of procedure appealed so strongly to those who practiced it, that he hoped he would be pardoned for again rehearsing its details and emphasizing its advantages.

Dr. Eastman then described his method of performing vaginal hysterectomy in detail.

Dr. FERNAND HENROTHIN had seen Dr. Eastman do the operation he had described, very skilfully and beautifully, and considered it at the time a very ingenious method of bringing the uterus into view. Relative to the use of the cautery, he had employed it in every instance of malignant disease of the uterus for several years, believing there was always an advantage in feeling that the tissues were burnt out in this way.

Dr. EMIL RIES thought the time for vaginal extirpation of the uterus had passed if the organ was carcinomatous, for the reason that the surgeon by removing this organ alone could not entirely get rid of the carcinomatous process.

The discussion was closed by Dr. Eastman.

Dr. E. E. MONTGOMERY of Philadelphia followed with a paper entitled

REMOVAL OF FIBROID TUMORS OF THE UTERUS WITHOUT HYSTERECTOMY.

He said that in presenting this subject he did not claim to reveal a new surgical device: for, the removal of such growths, without the sacrifice of the uterus, had been done by many operators a number of years since. In view of the hesitancy of many women to undergo a sacrificial operation and of the prolonged and unpleasant phenomena consequent upon a premature establishment of the menopause, he emphasized the employment of the procedure under consideration as an alternative for hysterectomy. There were, he believed, at the present day, but few operators who preferred hysterectomy to myomectomy for distinctly pedunculated subperitoneal or submucous fibroids, but there was a large number of cases in which the organ was occupied by an interstitial or a sessile submucous fibroid, or by many growths of all varieties, as classified by situation, where a healthy functioning organ could still be retained after the removal of the growths. Such practice with proper aseptic precautions was in his opinion attended with less shock and discomfort to the patient than

the apparently more simple operation of extirpation of the diseased organ.

The choice of route, whether vaginal or abdominal, depends upon the situation and size of the growth. All pedunculated or sessile submucous and interstitial fibroids, not too large to pass through the pelvis, should be attacked through the vagina. When the growth is so large that it rests above the brim of the pelvis, or the uterus is occupied by a large number of growths, possibly comprising every variety, the abdominal route was preferable. Of course, it could not be questioned that there were cases in which the uterine structure was so occupied by growths as to preclude the possibility of their removal with any hope of the subsequent retention of the uterus, nor would the retention of the uterus be good practice where the presence of growths was complicated by the existence of irrecoverable double tubal or ovarian disease. By either the vaginal or abdominal route, in the majority of cases, the procedure was mainly a process of enucleation in which a blunt dissector and not the fingers should play the important rôle. The enucleation can thus be accomplished through a minimum incision with less danger of infection. Small sized growths of the submucous variety which have partially or completely dilated the cervix, present but little difficulty in either diagnosis or treatment. If the cervix is insufficiently dilated to permit its investigation and exit, a bilateral incision can be made and the tumor removed. It is when the growth is situated within the body with the cervix long and undilated that the difficulty presents. Here a careful investigation of the situation and relation of the growth is an important prerequisite to any operative procedure. Such an investigation is only secured by a dilatation of the canal that will permit of digital exploration. This may be accomplished by repeated packing with gauze (Vulliet's method), dilatation with bougies (Hegar's), the use of tents, or bilateral incision of the cervix to or beyond the internal os (Pean's). The latter procedure seems too severe a measure for mere diagnostic purposes; will prove unnecessary for the removal of some growths, and the situation of the incision will prove impracticable or embarrassing in the treatment of others. Dilatation by gauze packing is generally slow, frequently ineffective. Bougies will result in tearing before the canal is open sufficiently to admit the finger. Dilatation by tents is the most satisfactory. Sponge tents accomplish the dilatation most rapidly, but are so difficult to render aseptic, and so easily infected, that their employment is dangerous. The hollow laminaria tent of good size will in the course of twelve hours in the majority of cases render digital exploration possible. Where the dilatation is incomplete it may then be safely effected by the use of bougies. If the surgeon is not prepared for operation at the time of investigation, the dilatation secured may be maintained twenty-four hours by gauze packing. It must be understood, however, that in all these procedures the most rigid asepsis must be practiced.

Having rendered the tumor accessible to the touch, further procedure must depend upon its situation, size and relation. A small pedunculated tumor will in this manner be rendered almost as accessible to manipulation as if situated in the cervix. Dr. Montgomery then reported cases illustrating the use of myomectomy without the removal of the uterus.

Dr. FRANKLIN H. MARTIN thought that in tumors involving the uterus to the extent of some of those described by the operator a hysterectomy would be a much easier and better procedure.

Dr. ALBERT GOLDSPOHN reported the case of a woman, 37 years of age, recently married, three months pregnant, who had a single fibroid tumor in the left wall of the uterus, so low down as to act a barrier to pregnancy. He did a panhysterectomy. If this was not the right course to pursue in such a case, he would like to know it.

Dr. N. SENN stated that it was important in transperitoneal myomectomy to make the incision very small, using the knife as little as possible, the enucleation being done largely by the director. The more he had resorted to this method the better he liked it and believes it to be an ideal way to treat by operative procedure uterine myofibromata in all cases in which such a method was possible anatomically or pathologically. He had made it a rule recently to invariably make the incision transversely, for the reason that it minimized one of the dangers attending this operation—hemorrhage.

Dr. C. A. L. REED of Cincinnati said that with the French treatment of *morellement*, with the American practice of myomectomy, he believes we are saving organs today which a few years ago were sacrificed, not to unwarranted zeal, but to the fact that our knowledge had not yet attained that precision and accuracy which enabled us to deal with these cases as we deal with them today. The trend of operative gynecology was in the direction of practical conservatism.

Dr. E. C. DUDLEY had no doubt whatever that a large number of cases of uterine myomata could be treated satisfactorily and safely by the method described by the essayist. In all of his operations during the past ten or twelve years, he should say that more than one-half of the tumors had been removed by myomectomy and the uterus retained.

Dr. FERNAND HENROTIN spoke in favor of vaginal enucleation of fibroids, whether intramural or submucous. He does not think there is any operation in gynecology so satisfactory as the morcellation of a growth sufficiently large to indicate it, or the enucleation of fibroid tumors through the vagina. It was folly, in his opinion, for any surgeon to attempt to enucleate a subperitoneal growth by the vagina which was situated well up in the abdomen.

Dr. C. S. BACON emphasized the method of enucleating uterine myomata through the vagina, and directed attention to the indications for it. He asked Dr. Montgomery whether any of the cases operated on by him had become pregnant and what was the course of pregnancy.

Dr. T. J. WATKINS referred to the disadvantages of myomectomy. The first of these was the presence of small nodules which later developed and caused trouble. The second disadvantage was the presence of soft fibroids, which had so much of the consistency of the uterus as to make it impossible to palpate them and remove them.

Dr. JOSEPH B. BACON reported a case in which he did a myomectomy and left the uterus intact. All things considered, he is satisfied that the woman would have had a better show and her life would have been saved had he performed hysterectomy. He hoped the essayist would keep track of the cases in which he had enucleated so many tumors, and at some future time inform the profession whether the women became pregnant, and as to the course of pregnancy.

Dr. A. H. FERGUSON cited a case in which he removed nine myomatous growths through the vagina, the woman being nine weeks pregnant. Most of the tumors were intramural.

Dr. FRANK A. STAHL asked Dr. Montgomery whether he found the use of tupelo tents exposed women to any particular danger.

Dr. MONTGOMERY, in closing, said he did not present a method of treatment which would save the uterus in every case. There were cases in which the uterus was involved to such an extent that hysterectomy would be preferable to myomectomy. In the case of Dr. Goldepohn, he thought a hysterectomy would be the preferable procedure. None of the cases operated on had thus far become pregnant. Replying to the question of Dr. Stahl, he said before a tent was introduced it should be placed a few minutes in a saturated solution of iodoform and ether, inserted into the canal, introducing iodoform upon the tent and keeping it in place. In those cases where he desired to explore the cavity to determine the condition, where he had used tents, he had not seen a single case of sepsis as a result. He would not use a tent in a case that had previously suffered from some inflammatory condition of the uterine or pelvic structures, parametric adhesions, etc., as he would be afraid to do so.

Dr. JOSEPH M. MATHEWS of Louisville followed with impromptu remarks, in which he made an eloquent

PLEA FOR EXAMINATION OF THE RECTUM IN OPERATIVE GYNECOLOGY.

He believes that all pathologic conditions involving the rectum could be made out by the touch without the use of instruments. Syphilis of the rectum was a disease that manifested but few symptoms. He had met cases where the only symptom complained of was constipation, but upon examination he had found the rectum blocked with a deposit. A lady consulted a gynecologist, who removed her ovaries. A few months after she consulted Dr. Mathews, and upon examination he found cancer of the rectum. He performed a Kraske operation. The point he desired to draw attention to was whether the rectum was examined by the gynecologist. He did not think so. He had reported five fatal cases of disease of the rectum that had been operated upon by gynecologists, and yet it was the rectal disease that ended life. The gynecologist, before doing any operation in the abdomen, should always make a careful examination of the rectum.

Association of American Anatomists.

Upon the invitation of Cornell University, the Association met at Ithaca, N. Y., Dec. 28-30, 1897. Morning and afternoon sessions were held on each of the three days excepting Wednesday, when all the affiliated societies met in the afternoon with the American Society of Naturalists. Notwithstanding the small attendance the sessions were fully occupied

with reports, papers and discussions, and several papers were read by title for lack of time. After a brief introductory by the President, Dr. Frank Baker, Dr. B. G. Wilder read an obituary notice of Dr. Harrison Allen, one of the founders and presidents of the Association. The report of the Secretary-treasurer, Dr. Lamb, showed that there were 105 active and 4 honorary members. Dr. Allen and Dr. Wm. Laurence Dana of Portland, Me., had died and Dr. P. J. McCourt of New York City had resigned. Beginning with the present year the annual dues are \$3. The circular and blanks in reference to the anatomic peculiarities of the negro race were ordered to be modified and copies sent out for report of cases. The Association adopted the report of the majority of the Committee on Anatomic Nomenclature and ordered it to be published and distributed as soon as practicable, accompanied by the objections of the minority of the Committee, and comments thereon by the Secretary of the Committee. Of the neural terms recommended, more than one hundred were identical with those adopted in 1895 by the Anatomische Gesellschaft.

The following papers were read and discussed; they were illustrated by specimens, photographs and diagrams:

P. A. Fish of Ithaca, N. Y., "A fluid for the retention of the natural colors of anatomic specimens," and "Mummification of small anatomic specimens." George S. Huntington of New York City, "Comparative anatomy and embryology as aids to the teaching of human anatomy in the medical course." Dr. Wilder, "An adult and healthy living cat, lacking the left arm, excepting the scapula, and having the heart apparently at the epigastrium." Woods Hutchinson of Buffalo, "Relative diameters of the human thorax." D. S. Lamb of Washington, D. C., "Pre-Columbian syphilis." Charles H. Ward of Rochester, N. Y., "A cranio-mandibular index." Prof. Howard Ayers of the University of Missouri, "The membrana basilaris, membrana tectoria and nerve endings in the human ear"; read by Dr. Hopkins. Dr. Wilder, "Certain resemblances and peculiarities of the human brain." B. B. Stroud of Ithaca, N. Y., "The ape cerebellum." Dr. Fish, "The brain of the fur seal, *Callorhinus ursinus*." Dr. Huntington, "The eparterial bronchial system of mammalia." J. A. Blake of New York City, "The relation of the bronchi to the thoracic wall." Thomas Dwight of Boston, "The distribution of the superior mesenteric artery." D. W. Montgomery, University of California, San Francisco, "Sebaceous glands in the mucous membrane of the mouth"; read by Dr. Lamb. Dr. Stroud, "Notes on the appendix." Prof. S. H. Gage of Ithaca, "On the relation of the ureters in the cat to the great veins; with variations." Dr. Wilder, "A number of specimens of either unusual or specially instructive character." H. A. Surace, Fellow in Cornell University, "Notes on the fish fauna of Cayuga Lake."

The following papers were read by title: Prof. George A. Dorsey of Chicago, "Description of two Koutenay skeletons," and "Two examples of unusual ossification of the first costal cartilages." E. R. Hodge of Washington, D. C., "Relation of sex to the size of the articular surfaces of the long bones." J. T. Duncan of Toronto, "Anus vulvalis." Woods Hutchinson, "A skin-heart?"

The following officers were elected for the ensuing term: B. G. Wilder of Ithaca, president; Geo. A. Piersol of Philadelphia, first vice-president; William Keiller of Galveston, Texas, second vice-president; D. S. Lamb, of Washington, D. C., secretary and treasurer; F. J. Brockway of New York City delegate, and R. W. Shufeldt of Washington alternate to Executive Committee of Congress of American Physicians and Surgeons; F. J. Shepherd of Montreal member of the Executive Committee of the Association, in place of Dr. Huntington, term expired.

The following candidates were elected active members of the Association: Frank Irving Brown, A.M., M.D., of South Portland, Me., instructor of anatomy, Portland School for Medical Instruction. George Amos Dorsey, A.B., Ph.D., acting curator of anthropology, Field Columbian Museum, Chicago. Grant Sherman Hopkins, D.Sc., assistant professor of anatomy, Cornell University. G. Carl Huber, M.D., assistant professor of histology, University of Michigan. A. T. Kerr, M.D., acting professor of anatomy, Medical Department, University of Buffalo. Alfred King, A.B., M.D., demonstrator of anatomy, Bowdoin College. Edward James McDonough, A.B., M.D., demonstrator of histology, Bowdoin College. John Anderson Springle, M.D., C.M., lecturer on anatomy, McGill University. Robert J. Terry, M.D., demonstrator of anatomy, Missouri Medical College, St. Louis. Prof. Albert H. Tuttle, D.Sc., University of Virginia.

The following eminent anatomists of the Old World were elected honorary members: Dr. Mathias Duval, Paris; Dr. Carl Gegenbaur, Heidelberg; Dr. Wilhelm His, Leipzig; Dr.

Albert von Kölliker, Würzburg; Dr. Alexander Macalister, Cambridge; Dr. L. Ranvier, Paris.

It is understood that the next meeting will be held in New York, during the Christmas holidays, in conjunction with the Society of Naturalists and other affiliated societies.

New Jersey State Sanitary Association.

(Concluded from page 557.)

Dr. B. MEADE BOLTON of Princeton read a paper on

VITALITY OF PATHOGENIC GERMS IN DRINKING WATER.

One of the most striking features of the bacteria is variability. These organisms are subject to variability of shape, of all these vital manifestations, such as fermentation, production of disease and of pigment, in the capacity of living in various media. They possess no characteristic not subject to variation. The anthrax bacillus, ordinarily a short sharply cut rod forming spores or resistant bodies under favorable conditions and capable of producing a virulent infectious disease in man and animals, sometimes becomes so distorted in shape as to be unrecognizable under the microscope. It may be made to lose its power of forming spores and of producing disease. The diphtheria bacillus is sometimes a fine uniformly stained rod; at others it appears as a large irregular nodular rod. Sometimes both ends are swollen and apparently distorted, sometimes one end alone. Again, the rod stains irregularly; the protoplasm is collected into clumps and granules in the cell membrane. The bacillus prodigiosus frequently resembles a coccus, and at others appears as a distinct rod or even a short thread. This organism which ordinarily forms a deep red mass on the nutrient medium, frequently loses its power of producing pigment. Percy Franklin has found out that with certain bacteria it is possible to force them to produce certain products of growth by gradually introducing certain substances into the nutrient medium. The speaker had found that the bacteria may be accustomed gradually to the presence of substances in the nutrient medium that would be sure to destroy or inhibit the growth. There is even evidence that the bacteria may be finally stimulated to increased growth by the gradual introduction of substances classed as germicides. But it is useless to multiply examples. The variability of the bacteria under the influence of external conditions is well recognized, and the sensibility of these to environment has been abundantly shown. This property must be ever borne in mind. It must not be forgotten that the bacteria are living cells, and not chemie compounds. All cells have more or less individuality, and all agglomerations of cells have variable characteristics. This can be illustrated by any series of experiments with disinfectants. The use of a certain amount of the disinfectant may destroy many of the organisms, and yet leave many more unaffected. The same amount of the disinfectant may kill more of the organisms in one culture than in another. Hence we can not wonder at the vitality of the bacteria in water. The typhoid fever bacillus has been found to live for thirty days in water into which it was introduced intentionally, and yet it is frequently found to die out much sooner than this in water. In many experiments he had endeavored to arrest the vitality of various pathogenic bacteria and the discrepancy in results was a surprise and a disappointment. Sometimes they diminished and disappeared much more quickly than at others. Yet this is not to be wondered at. There are many factors that determine how long they are likely to remain. The number introduced, the special adaptability to water of those that are introduced, the temperature of the water, the number of other kinds of bacilli present, all are factors in the play. Again, the amount of organic matter that could furnish a supply of nutrition might be a factor. He always found that pathogenic bacteria introduced into water disappear sooner or later. They do not multiply even in foul water from a shallow well, and fail even when this water was freed from other bacteria that is sterilized. He was able to obtain a multiplication in water only after he had added a certain amount of peptonized beef broth. It was necessary to add an amount of broth estimated to contain 67 milligrams of organic matter to a liter of water before any growth could be obtained of typhoid bacillus, and the equivalent of 400 milligrams of organic matter before any multiplication of the cholera organism could be obtained. This amount of organic matter is never found in the most contaminated water, and not only this, but the kind of organic matter used in the experiments is not found. What is found ordinarily would be less suitable for the typhoid and cholera bacilli than the carefully prepared peptonized broth used in the experiments, and it may safely be stated that where water becomes contaminated with pathogenic bacteria these will disappear

rapidly, owing to lack of proper nutrition and to the conflict of other bacteria, the saprophytes, found always in contaminated water. There are bacteria that multiply even in distilled water, and these are the aquatic bacteria which quickly make the pathogenic form disappear. The latter are very choice in their food. We must prepare the media for their cultivation with great care, and they stand no chance in competition with the hardy saprophytes found in water. The pathogenic must be given conditions closely resembling those of the animal body to grow and multiply; the saprophytes, on the other hand, flourish at a lower temperature and with less elaborate food. This is the reason why the examination of water shipped to the laboratory is of no use. In a few hours it is changed as to its flora, some abundant at first are less so; others, few at the start, increase often enormously. It is an interesting experiment to examine water freshly caught, let it stand and examine at intervals. About two forms usually survive and increase very rapidly. One is a bacillus fluorescent, non-liquefactive, and a micrococcus, to which he gave the name micrococcus aqualilis. For this reason it is never worth while to attempt an analysis of shipped water.

Results are misleading. The danger from contaminated water arises from the use of the water very shortly after contamination. Of course, if there is a source of continuous contamination, then the water is dangerous at all times, and the organisms are easily found, as during the cholera epidemic of Hamburg and Altona. In case of typhoid the matter is peculiarly difficult and time-consuming. Again, another difficulty is the want of definite characteristics of typhoid bacilli themselves. The matter of contamination of water with this form is of more importance to us in this latitude, and it would be of the greatest value to be able easily to recognize this organism. Satisfactory results are not obtainable without the expenditure of a great amount of work and many precautions in the collection of samples, and immediately making cultures. He questioned the utility of one examination. A well may be free and contaminated at different times. The chief if not the only danger arises from surface contamination. If water filters through a soil it is purified. Now, during a dry season, there is little danger from the surface drainage. Only in case there is a crack or crevice leading from a privy vault or other source of contamination is there great danger of infection. Esmarch has shown that pathogenic bacteria rapidly die out in the soil within one or two days, so that it would be a difficult matter really to make the bacteria pass from a privy vault to a well through soil in which there are no crevices. Flügge is of opinion that infection of water is more apt to take place indirectly than directly. He does not deny any more than others that what the Germans call "massen infection" takes place from drinking water. In the case of typhoid fever Dr. Bolton always believed that danger of spreading the disease arises as much from indirect contact of food and vessels, for food and drink, with the typhoid excreta as from contaminated water. Finally, pathogenic bacteria usually have a brief life in water; under ordinary conditions multiplication and growth are not favored; the danger of the spread of the disease in this way is transitory unless the source of contamination is continuous as from a channel leading from a privy vault. Water is probably infected frequently after it is drawn and carried into the house for use just as food probably is.

Mr. H. B. BALDWIN, chemist of the Newark Board of Health, said we may search for a long time in the literature of the subject and not get such definite information. It is well to know what conditions favor or destroy the growth of bacteria in open supplies. In the case of surface water it is important to know definitely what conditions affect the vitality of pathogenic germs, as it is supplies of this character that usually cause the most serious epidemics. It is also in such areas usually impossible to find the germ on account of dilution or to the fact of the absence when looked for; in the case of ground water the action of the soil on the vitality of the bacteria is most important. In London, a few years ago, the relation of cholera spirillum and typhoid bacillus was discussed. Experiments were made in sterilized soils of white sand, yellow and garden earth, and peat under various conditions of moisture. It was found that the cholera germ in dry soil did not live more than two or three days; in ordinary dry soil, about three days; in moist white sand, seven days; in moist yellow sand and garden earth, thirty-three days; and under certain conditions of moisture and evaporation, the germs were alive at the end of 174 days, the life-supporting power of white sand being the least. In peat, death always occurred in about twenty-four hours, notwithstanding the amount of moisture. The typhoid bacilli in ordinary dry soil were found up to the ninth day in the white sand; to the eighteenth in yellow and to the fourteenth in garden earth. In moist white sand they were alive on the

twenty-third day; in yellow sand and garden earth on the forty-second day. Peat caused death in twenty-four hours. Now, in view of the destructive action of peat it seems reasonable to suppose that peaty waters, so plentiful in this State, would excite an unfavorable action on the growth of bacteria contained therein. Miquel says when samples of various waters, pure and impure, are maintained at a constant temperature of 68 degrees F., they vary differently in the matter of the increase of their bacterial contents. With pure water the increase is rapid and temporary, while with impure water it is slow and lasting. The decrease of bacteria when intentionally introduced into water is due no doubt to the presence of toxins produced either by these or other bacteria. These toxins are very volatile and the following interesting experiments by Prof. Martin furnish, in a striking manner, the deadly effect of the toxins on bacteria. Some water slowly distilled in a special apparatus at a temperature between 86 and 95 degrees, was inoculated with the germs from 1650 liters of air. The number of bacteria found in the water were: immediately 75 per cent.; six days later, 7 per cent.; sixteen days later, 1.5 per cent. Note the difference between this and the next experiment. River water sterilized in the ordinary manner was inoculated with germs from twenty liters of air. The number of bacteria per cubic centimeter was then 6.5 per cent.; seven days later, 750,000 per cent.; ten days, 900,000 per cent.; thirty-one days, 16,750,000 per cent.; ninety days, 62,500 per cent.; 273 days, 48,000 per cent. In a paper read before the American Chemical Society by Dr. Dunham, he states: The chief aim of the examination of water with reference to its fitness for drinking, is to learn whether it contains, or is likely to contain, any poisonous substances or the contagion of disease. The detection of mineral poison falls within the domain of chemistry. The actual isolation of specific bacteria can only be done by bacteriologic methods; true so far as it goes, but he only stated the smaller part for the chemist; leaving out the question as to the possible extent to which the bacteriologic examination may be pushed, the practical and usual examination consists of counting the number of bacteria per cubic centimeter, and searching for the typhoid bacillus and the bacillus coli communis. The latter as a constant quantity in feces, indicates sewage pollution. The typhoid bacillus is rarely found in drinking water, although most positively known to be present. This leaves the colon bacillus as the main evidence of the bacteriologist of sewage contamination. As he does not find the pathogenic germ he can not do more than class the water as dangerous.

It should be remembered that the bacteriologist looks for something that is in suspension, while the chemist determines substances in solution. The bacillus may, in the case of well water, be temporarily filtered, while other soluble matters are not affected. On the other hand, the polluting matter may be so largely diluted that chemic tests will fail to reveal it, and yet there may be enough coli bacilli to give a positive indication. As an illustration, a few days ago he had examined some water from a well situated within a few feet of a cesspool and found it grossly polluted. A bacteriologic examination failed to reveal any coli bacilli, and pronounced the water safe. Here the bacilli had been filtered out by the soil. But who knows what day they may come again, or rather through the soil filter? The city supply of Newark furnishes an example of the other condition. Any one who has seen the water shed can not doubt the presence of coli bacilli constantly in that water, as it has been for years; yet chemically, the water is of excellent quality. This is not the fault of the bacteriologist: there simply did not happen to be any germs in the few drops he examined. Do not understand me to belittle the work of the bacteriologist, said Dr. Baldwin; his aid is of the highest advantage, but it will readily be seen that there may be many cases where either form of examination would give positive results, and hence for safety, in all cases both must be employed, as each supplements the other.

Dr. N. L. Wilson of Elizabeth read a paper on

NOTIFICATION OF MEASLES AND WHOOPING COUGH.

He said: There were 275 deaths from whooping cough in New Jersey and 390 of measles during 1896. The first carried off more than the average of persons during the last eighteen years. Measles gave 2907 deaths, a low estimate because cases of both are not always properly recognized, and in many instances the primary cause of death is not given. In the last eight years there were 2223 of whooping cough and 1354 of measles. The majority of the profession are of the belief that we can not restrict the spread of either disease, because of their communicability at such an early period. The question is simply one of expense. Notification of measles without corresponding disinfection, isolation, etc., is useless. They could be limited

if properly cared for and the work carried out. Great success attended the work in this way in Birmingham. He mentioned a case where a child had measles, recovered, the family removed. In two weeks a child of the new family who moved in had measles and died from bronchial pneumonia. Here, isolation in one room and prompt disinfection would have saved the last child. Disinfection can not be done unless notification is insisted upon. While we acknowledge the difficulties in the case, yet it is worth an effort. Measles respects nothing but sanitation. This muzzles it and makes the epidemic milder. The etiology of measles shows it to be intensely contagious all the time, most at full efflorescence, less in the period of incubation and least or not at all after desquamation. It is not believed that we have found the specific organism of either. Whittaker says, "prophylaxis is almost impossible, but sickly, debilitated children should be removed from the house where it exists." All know how an epidemic will run through schools. One hundred and twenty cases were confined to the pupils of one parochial school. When asked how this was, the reply was: It is a simple matter; the teachers were required each morning to ask the scholars as to the presence of sickness at home or in the neighborhood. In case of an affirmative, the scholar was not to come in the afternoon. The names and addresses were sent to the chief teacher, who investigated the case, and thus the spread was prevented. The public schools of Elizabeth are connected by telephone; the health inspector communicated with the superintendent of schools each morning; he notified the principals of the various schools, so that they are familiar with the number and cause of disease in their respective schools. If the physician or parents fail to report either of these diseases we can not attempt to check them. He was heartily in favor of notification. It is the duty of the parents and of the physician to do this whenever they can. There may be difficulties in the way of inhibition of the two diseases, but we should at least establish the practice, and undoubtedly the death rate would be reduced and life among children prolonged.

In the discussion two or three opposed notification, but this appeared to come from those not of advanced ideas as to etiology of disease, while the consensus of opinion, though not expressed by the continuation of the discussion, was decidedly in favor. As there were several matters of business demanding the attention of the Association prior to closing the session, these gentlemen did not care to spend the time when, as one very prominent member remarked, such views were utterly in opposition to all sanitary knowledge.

The officers elected for the next year were: President, Dr. John C. Smock of Trenton; vice-presidents, V. L. Davey of East Orange; Dr. Daniel Strock of Camden and G. W. Howell, C. E., of Morristown; recording secretary, Dr. James A. Epton of Arlington; corresponding secretary, W. G. Hoopes of Atlantic City; treasurer, Geo. C. Olcott, C. E., of East Orange.

SELECTIONS.

Hygiene of Degeneracy as Illustrated by Charles and Mary Lamb.

Dr. Kiernan recently presented to the Chicago Academy of Medicine, a paper on this subject. He pointed out that the paternal branch of the Lamb family came from the fens of Lincolnshire where laudanum using is rife, albeit with comparative immunity from the usual effects of opiphagism. In these districts, where degeneracy of type is frequent but ascribed to malaria, John Lamb, the father of Charles, was born. While still a child John Lamb's family removed to Lincoln so poverty-stricken because of the insanity of its head that he had to be made a foot-boy. The fact that he subsequently became barrister's clerk indicates gentler early nurture than this early thrusting into the fierce struggle for existence would seem to imply. John Lamb grew up gay, inflexibly upright, with a dash of chivalry in his nature and a poetic tendency. At the age of 50 years he became insane and died demented. His sister was an uncanny old soul, whose silent ways and odder witch like mutterings and mumblings, coupled with a wild look in her eyes as she peered out from under her spectacles made her an object of dread. The maternal ancestry was neuropathic. The mother exhibited the capricious affection often present in the degenerate. The maternal grandmother had that moral anesthesia toward mental suffer-

ing which is an offspring of degeneracy. Elizabeth Field, many years younger than John Lamb, her husband, was a handsome, dignified, pleasure-seeking hysteric, lacking insight into child character. Toward Mary and Charles she never manifested maternal tenderness. Mary, a shy, sensitive, nervous, affectionate child, who early evinced liability to brain disorder, peculiarly needed judicious care. The mother always loved John, the eldest, a handsome, lively boy, who became what favoritism was sure to make of an egotist; treated with indulgence by brother and sister who exempted him from any share of the family burden even when he was prosperous. Mary Anne Lamb, born Dec. 3, 1764, was the third, while Charles was the youngest of seven children. All died in infancy save John, Mary and Charles. Mary Lamb was brought up in a lower middle-class home relieved alike from the stress of poverty and speculative wealth. She received her education in a day school. The best of her education was the library of her father's employer. Here she was early left to browse without prohibition on the principle advocated by Ruskin. The degenerate absence of that finer sympathy of human nature in its most alluring aspect eminently unfitted Mary's mother and grandmother for the training of a neurotic child. The primary *ego* so prominent in degenerates while decidedly obtrusive in John, Mrs. Lamb and Mrs. Field, was wonderfully subordinate in Mary and Charles Lamb for children of such heredity. Charles, a weakly child, had frequent night terrors, learned to speak with difficulty and stammered throughout life. The pleasure-seeking nature of his mother, whose maternal tenderness like that of most hysterics had been exhausted on her first-born, devolved his care upon Mary, who mothered him. This outlet for her affection naturally dispelled her loneliness. In after life she warmly described the wholesome influence upon her troubled mind which devotion to Charles brought. As his mind unfolded he still found in her that genial care which had cherished his frame into health. With his hand in hers he first trod the Temple Gardens, spelled out the inscriptions on the sun-dial and on the tombstones in the old burying ground and wondered, finding only the virtuous, "where all the naughty people were buried." The familiar features of the neurotic child appear in the autobiographical sketch Charles Lamb contributed to "Mrs. Leicester's School."

In the Lamb household the domestic outlook grew dark as soon as Mary was grown up. Her father's faculties received a shock and her mother became a paralytic hysteric. At 15 years of age Charles left Christ's Hospital to take up the burdens of an adult. Mary had not only to make head against sickness, helplessness and old age, but to support the family by millinery. She employed herself thus from the age of 21 to 32. When Mary was 30 and Charles 20, the father fallen into dementia had been pensioned off by his employers. Charles, under the stress of puberty, of an unfortunate love affair, and of his struggles to support the family neglected by John, became so insane as to require hospital care. He was able to resume his usual labors as clerk in the India house after six weeks treatment. The psychosis was that unstable type of melancholia so frequent in degenerates, in which flashes of exultation through the emotional gloom are remembered with keen rapture. No sooner was Charles recovered than John met with a serious accident. Whilst in health he had spent his earnings on himself; he did not hesitate to demand home nursing, causing renewed anxiety to his brother and sister. This was the last ounce. Mary, worn out with years of nightly and daily attendance upon a demented father and a hysterically paraplegic mother, harassed by a close application to millinery, was strained beyond physical endurance. About Sept. 15, 1796, the family observed mental symptoms which had so increased by September 21 that Charles early in the morning sought but failed to find Dr. Pitcairn. That afternoon Mary, seized with a sudden frenzy, snatched a knife

from the table, pursued the apprentice, when her mother interposing was stabbed, dying instantly. Mary was placed in a private insane hospital where she in a short time recovered, but subsequently became a cyclothymiac. Such a combination of depressing factors constituting a proper etiologic moment would suffice, even in an organization with little or no morbid heredity, to produce a serious transitory frenzy without consciousness of the violent act. The two careers of Mary and Charles Lamb illustrate how, even under the burden of inherited degeneracy and the no less terrible strain of an environment entailing a fierce struggle for existence, a large amount of soundness of intellect and morality may survive. They also illustrate the beneficence of physiologic atavism causing continual attempts to regain a normal type lost for some generations. In Charles Lamb's career there is much to indicate that had dietetics been as well understood then as today, much of his sufferings and so-called eccentricities might have been avoided. The childhood of both Mary and John Lamb demonstrates how readily, in minds of degenerates or of persons at a certain state of culture, the germs of unwholesome atavistic beliefs are created to form the basis of much that proved absurd and even dangerous in after life, despite careful education subsequent to puberty. The two cases also illustrate very fully, since both Charles and his sister were ardent students of the older English dramatists and the older English literature, how much unwholesomeness there lies in this as contrasted with works on emotional religion or dogmatic theology. Charles and Mary were both unquestionably devout but with a certain largeness of view which proved a source of mental hygiene in place of a poison like most dogmatic theology and religiosity. Undoubtedly Mary's religious views tended to comfort her when she discovered that she had slain her mother during a fit of insanity. Her mental state, however, differed decidedly from that moral anesthesia produced in certain insane by a hospital sojourn, which makes them so delightfully altruistic within the walls and so brutally egotistic without. Charles Lamb's mental breakdown, which occurred at the decidedly critical period of puberty, illustrates the benefit of hospital care and the folly of home treatment.

The Abuse of Medical Charity: A Critical Review of Recent Literature.—Dr. Frederick Holme Wiggin of New York read a paper with this title before the New York State Medical Association, Oct. 12, 1897. His object was not so much to present individual views as to cull from recent literature, both lay and medical, the opinions of many writers. He said that it was easy to demonstrate conclusively that as at present administered medical charity is demoralizing to both the recipients and the donor. Some idea of the alarming growth and extent of this evil might be obtained from the carefully prepared report of Dr. Stephen Smith to the State Board of Charity. Here it was shown that during the year 1895, 837,971 persons applied for and received free medical treatment at 105 dispensaries in that city; that 1,418,847 free visits were made by these applicants to these dispensaries; and that 78,000 persons received free board, lodging, nursing, drugs, surgical dressings and treatment; in other words, that something more than 40 per cent. of all who live within our borders had claimed in one year to be unable to care for themselves. This should be contrasted with another statement by Dr. Smith to the effect that during the period from 1791, when the first dispensary was established in New York, to about 1870, the applicants for charity bore a ratio to the total population of 1.5 per cent. Dr. Wiggin then went on to quote from an editorial in the *New York Herald* to show that Greater New York spent fifty millions of dollars every year on charities, and that according to a conservative estimate fully 50 per cent. of the donors' money was diverted from the purpose for which it was intended and was practically filched from the poor to whom it rightfully

belonged. Again, according to one author, Dr. J. B. Huber, one might find in large numbers at dispensaries such people as actors, opera singers, gamblers, bartenders, policemen, farmers from out of town, prosperous business men and those owning houses, lawyers, and perhaps even a street railway president. According to another author, Dr. George F. Shrady, fully 50 per cent. of the applicants in the reception room of a well-known institution, which he dubs "the diamond dispensary," were well dressed, 10 per cent. were finely dressed, more than half of the men bore no evidence of poverty, and among the women there was an attractive display of fine millinery; yet all obtained the free treatment supposed to be given only to poor persons. A reporter on one of the daily papers, in describing what he saw at a well-known "clinic," stated that not more than one in fifty was at all shabbily dressed, a large majority were fairly well dressed, one-third of them were quite presentably dressed, and perhaps one fifth were positively well dressed. The reader of the paper said that he knew of a man who paid an enormous rent in a fashionable apartment house near Central Park, and who spent many thousand dollars a year on living expenses, yet he went to what Dr. Shrady had so aptly termed "the diamond dispensary" on the plea that his expenses were so heavy that he could not afford to pay a fee to a doctor. Surely, the author continues, these instances "certainly show the spirit in which charity is asked for and accepted; it is largely a desire to save money, without apparently thinking that self-respect is lost in the effort, or that a wrong is done to the really poor and to the physician, who is certainly as much entitled to his hire as the clergyman, or other members of the community, as he too has social obligations to fulfill." More than this, as Dr. Schweck had well said, in the *Philadelphia Press*: "People of means who go to charity dispensaries and receive treatment free of charge, representing themselves to be too poor to pay for medical services, commit a criminal act, for they obtain what they are not entitled to and do it under false pretenses." Another and important aspect of this subject had been revealed in a communication from Dr. G. M. Roe, Medical Superintendent of the Boston City Hospital, to the *Boston Herald*. He says: "It is a generally accepted fact among people who have had large experience in doing charitable work that the first thing that a man or woman will accept as charity is medical attendance. They will accept free service of the doctor when you could not prevail upon them to accept rent or fuel or anything of the kind as a gift. The acceptance of gratuitous medical attendance is the first step toward pauperism. There is already a tendency toward what is generally known as 'nationalism,' a belief among the common people that the city and State owe them a living, and that medical attendance, among other things, should be furnished them by common taxation, regardless of their financial standing as individuals." Again, as Dr. J. J. Stevenson has expressed it in the *Mail and Express*: "If recovery from disease be secured at the expense of self-denial, the memory of the cost will lead, in ordinary cases, to care that a recurrence of disease and attendant expenses may be prevented. But if the careless feel that treatment, medicine and even diet can be had simply for the asking, there can be no reason for resisting the natural tendency to neglect the laws of health. . . . It is not surprising that the reckless poor see in such carelessness giving an acknowledgement of the unequal distribution of wealth and believe that it is founded on injustice; nor is it strange that the anarchist's cry is not for opportunity to earn by labor, but for such distribution of wealth as may enable all to enjoy the luxury of idleness." The following are the conclusions arrived at by Dr. Wiggan after a critical review of the subject: 1, that medical charity as at present administered is an unqualified evil, and is seriously menacing our existing social conditions; 2, that the application for free treatment of those able to pay the physician a moderate fee for his services robs the really poor; 3, that all medical charitable institutions should be under the direction and control of State and local boards of charities, who should have the power to enforce their rules; 4, that all applicants for medical charity should be investigated by local charity boards and the unworthy excluded; 5, that no medical charitable institution should be allowed to charge nominal sums for medical or surgical service, nor should they be allowed to charge for medicines or appliances; 6, that all physicians connected with charitable institutions should be paid for the service which they render; 7, that it should be made a misde-

meanor, punishable by fine for any person to receive free medical treatment by reason of false representations as to financial condition, and 8, that State or city aid should not be granted to private medical charities.

PRAGTICAL NOTES.

Therapy of Sulphate of Duboisin.—This preparation may be used both by the mouth and hypodermatically; preferably by the latter. Among the indications for and against its use are the following: Cases of excitement due to hallucinations and delusions give excellent results. In all forms of chronic insanity with excitement, and in occasional cases of epilepsy, it may be used as a sedative with good results. The author concludes that duboisin should be used only in physically healthy persons. It should never be used, or only very carefully in debilitated persons. It is not suited to acute mania, and is distinctly injurious in melancholia. Duboisin is preferable to hyoscin or hyoscyanin, as the quiescent state established by its use is of longer duration, and there is less prostration during or after its use than is the case with those drugs. The after-effects are not so marked, and few serious cases occur. Its action in some of the worst cases is described by the patients as soothing rather than prostrating, and it does not interfere with the recovery of those treated with it.—*British Medical Journal*.

Surgical Treatment of Hematemesis.—Cazin recently operated on two cases of fulminating hematemesis, one caused by a gunshot wound into the stomach, the bullet passing out through the intestines, the other by a few slight erosions on the posterior wall of the stomach, from which the blood was pouring in sheets. Dieulafoy reports a similar case and is inclined to consider these slight superficial erosions the incipient stage of an ulcer, proposing the name "exulceratio simplex." In both of Cazin's cases recovery was prompt and complete after the stomach had been opened up largely and a few stitches taken in the bleeding points. He ascribes his success to the intravenous injection of one and one-half liters of artificial serum during the operation and again in the evening, as the patients were exsanguinated and ready to collapse. Roux has also had a similar experience in the case of an ulcer which he resected. Marion in his thesis collected six observations, three fatal. Fournier relates several cases of copious and repeated hematemesis in syphilitics, promptly cured with specific treatment after all other medical means had failed. He claims a place for syphilis in the etiology of *ulcus rotundum*.—*Bull. de l'Acad. de Méd.*, January 18-25.

Glycerin Condoms for Artificial Abortion.—The experience that intra-uterine injections of glycerin were followed by intoxication, injury to the renal parenchyma, destruction of the red corpuscles, chills, dyspnea, etc., has caused them to be rejected by many, although the fact is universally recognized that glycerin is the most prompt and reliable of all means to induce contractions of the gravid uterus. H. Saft of Breslau announces that this power is due to the hygroscopic properties of glycerin. It draws the water out of the tissues and out of the nerves and ganglia, thus stimulating the latter to induce contractions. As the glycerin is absorbed by the blood it draws the water out of the corpuscles; they shrivel, die and dissolve. He has devised a means to use glycerin without allowing it to be absorbed, introducing it in an ordinary fish-bladder condom, sterilized by the Schimmelbusch process of sterilizing catgut (ether, sublimate, alcohol). The condom does not interfere in the least with the hygroscopic action of the glycerin through its membrane walls, but it prevents the absorption of any considerable amount of glycerin into the organism. The condom is inserted empty on a bougie to which it is fastened, the end projecting 2 cm. to avoid tearing. It is then filled through the bougie with 100 cm. glycerin and the mouth tied with an elastic cord to pre-

vent the escape of the glycerin. The bougie is cut to the right length to ensure its correct position between the fetal membranes and the uterus, the outer end just reaching to the entrance of the vagina, which is closed with a cotton pad. The glycerin condom acts as a foreign body while the glycerin exerts its peculiar properties safely through its walls. The condom must be tested and water-tight membranes rejected. Saft is now testing other substances with high endosmotic power to find one equally efficient and absolutely harmless, to substitute for the glycerin, such as sodium sulphate.—*Deu. Med. Woch.*, January 20.

The Grippe and its Therapeutics.—All our European exchanges refer to the prevailing epidemic of grippe, which is raising the death rate everywhere. Maragliano notes the indirect action of the grippe in cases of existing disease, usually manifested in disturbances of the nervous system, especially in disturbed cerebral functions. He has thus observed meningitic manifestations in broncho-pneumonitis, in intestinal catarrh or simple sciatica, in which they are an unusual complication. Another remarkable fact is the tendency of the pyogenic cocci to locate wherever there is a favorable soil starting at once into virulent action; for instance he notes pleuritis commencing pyogenic from the start, broncho-pneumonitis with streptococcal infection and lobar pneumonitis with notable pyogenic manifestations. The rapid appearance of congestive or hemorrhagic phenomena in affections usually free from them, is another feature of the epidemic. Quinin in sufficient doses, he adds, constitutes an almost specific remedy. *Gazetta d. Osp. e d. Clin.*, January 23.

Re-education of the Muscles and Nerves in Tabes is justly considered a great advance in the therapeutics of this affection. E. Frenkel's system is now supplemented by others seeking to educate the muscles of the inferior members. Goldscheider and Leyden have devised various apparatuses for restoring the disturbed co-ordination by exercises that establish compensation. Some of them are described and illustrated in the *Deu. Med. Woch.*, of January 27 and February 3, which seem destined to accomplish remarkable results in this line, requiring sufficient attention to divert the mind and render the exercise interesting. The influence of suggestion is also important. One is a row of shallow wooden goblets on a sloping shelf, with a similar shelf above and below, in front of which the patient sits, and touches with the tip of his foot the various goblets in turn or alternately from shelf to shelf. Balls in the goblets are to be touched without pushing them out. Another is a narrow platform with hand rails and triangular slabs set upright in the floor at intervals, over which the patient steps. Their position can be altered at will. Another is a spiral marked on the floor, along which the patient walks, supporting himself by a rope from above. Another is a small ladder; the patient seated, inserts the tip of his foot between the rounds in turn. The patient's leg is assisted by an attendant whenever necessary. Simpler exercises are accomplished reclining, with a frame from which the leg is suspended. They urge the advantages to be derived from simple exercises of the limbs in a bath, when they are buoyed up by the water salts. Goldscheider is now experimenting with a bath for the purpose in which the patient can stand erect with his body under water. Leyden by the way, rejects the syphilitic etiology of tabes, which he has always ascribed to "sensibility disturbances." Gutzmann has recently called attention to the great benefit to be derived from the mirror in re-educating the muscles, controlling their work by the eye. He separates the muscular act into its component parts and has it performed thus in sections, before a mirror.

Asphyxia Neonatorum.—Richard Hogner, M.D., Boston, Mass., thus describes his method of treatment: The operator seats himself on a high chair; has a tub of lukewarm water placed on the floor at his right hand, with vessels of both hot and cold water within easy reaching distance. He holds his legs together—somewhat bent at the knees—and in an inclined plane; lays his left arm (if he be right-handed) with the "palma manus" turned upward upon the "femores," so

that the wrist rests between his knees, and the open hand, with the fingers spread, is free in the air. The child is laid head downward on its back along the operator's left arm, so that the head and shoulders can be supported by the fingers and the infant securely held. The child's body must be sufficiently inclined downward so that the phlegm, edema, etc., can easily run out through the nostrils, and its arms must be outstretched and hanging backward and downward sufficiently to hold the pectoral muscles in the greatest tension, bringing the chest into the maximal position of inspiration. The operator now lays his right hand, with fingers extended, down over the child's breast and abdomen, so the tip of the middle finger rests on the throat, the index and the ring finger on the subclavicular regions, and the thumb and little finger in the armpits. By pressing with the fingers of the right hand on the chest and with the palm on the abdomen, artificial expiration is induced, followed, as soon as the pressure is removed, by an automatic inspiratory movement, which is caused solely by the above described wide-open, over-hanging position. If the operator now continues in right tempo (preferably too slowly than too rapidly) to alternate with the pressure and non-pressure of the hand, he can induce artificial respiration of whatever rapidity or depth required.

The frothy substance, often bloody phlegm, etc., which will escape from the child's nose, can be removed as it appears, or one can leave it to itself, because the position the child occupies, with head downward, prevents these secretions from being drawn into the windpipe.

Between the breathing movements, I am accustomed to try to stimulate the tone of the heart by means of delicate percussions on the precordial region in rhythm with the heart beats, which are most easily made by means of the middle and ring fingers, without otherwise changing the position of the right hand. There is a similar movement employed in Swedish medical gymnastics to great advantage in cases of heart failure, a movement which has proven its mechanically reflective influence on the action of the heart, which becomes stronger, also slower, or more rapid, according to the tempo of the movement.

The position of the child is now and then changed to an upright one, partly to empty the bronchi, which has not become drained by the child's downward position, and partly to relieve the auriculi of the heart, at which time, if it seems advisable, the operator dips the child into the bathtub beside him, into the hot water, and then cold water is sprinkled on its breast, etc.

In employing this method the position of the physician is so comfortable that he can continue the operation uninterruptedly for more than two hours, which should be, according to authorities, the shortest length of time generally to devote in efforts for resuscitation of the infant before hope is abandoned. During the process the child undergoes a drainage of most of the respiratory tubes. All necessary manipulations can easily be made, and at the same time the parents or friends are not distressed by methods that seem cruel, such as the swinging of the child in the air, the holding of it by the feet head downward, etc.

For subcutaneous injections as stimulants to the heart action of the new-born child, alcohol, ether and oil of camphor, have been recommended. I prefer the physiologic (or even stronger, 0.6 to 2 per cent.) salt solution, from a few drops to one-half c. cm. at a time. Equally good is perhaps an injection of nitroglycerin, recommended by Dr. J. R. Scott of Clay Center, Kansas, in the *Western Medical Journal* for March, 1897.

This is about the rule he follows: Take a tablet of 1-100 m., put it into a syringe which holds 60 m., expell one-half of the solution and fill the syringe again with water. Of this solution he used 5 m., which equaled 1-2400 of the drug.

I have never made use of nitroglycerin injections either in adults or children. On the other hand, I have often used injections of salt solutions and always with instantaneous effect.

Every time the above described method of treatment by artificial respiration, heart percussion and use of water of different temperatures has been employed the result was a happy one, with a single exception, where even Schultz's swinging was added, and all treatment failed.—*Times and Register*, Jan. 29, 1898.

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
 No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, 100 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the *Editor*, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, MARCH 12, 1898.

THE RELATION OF GLYCOSURIA TO DIABETES.

In the midst of the very conflicting statements which have been made by physicians and physiologists in regard to the etiology and pathology of this disease, the increasing frequency of which we have already called attention to in the JOURNAL, it may not be out of place to call attention to some of the facts which are known to exist in regard to the pathology of this malady. It is but a few years since we have been taught that the constant presence of albumin in the urine was a pathognomonic sign of parenchymatous nephritis, and indeed the temporary presence of albuminuria from time to time was thought to possess equal significance. Now we know that albuminuria in itself is not a pathognomonic indication of a renal lesion of a serious character, however indicative it may be of nephritic changes. So, too, some years ago it was generally considered that the presence of sugar in the urine was an indication of diabetes mellitus, but today those who know most about this condition recognize two states: one that of glycosuria; the other, true diabetes mellitus. In the former the presence of sugar in the urine is due to the excessive ingestion of carbohydrates or sugars; in the other the moderate ingestion of those foodstuffs are, to the individual who has diabetic tendencies, excessive, even though the quantities actually taken up are small, for while one individual may be able to assimilate large quantities of carbohydrate material, another individual fails to utilize even a smaller quantity of such substances; and while individuals who readily develop glycosuria when their powers of assimilation are slightly strained, may be considered as having a tendency to diabetes,

they certainly can not be considered as diabetics. They are simply leaky vessels unable to contain all the carbohydrate material which they ingest. That glycosuria can be produced experimentally in any individual by the ingestion of sugar has been proved by a number of investigations. Recently LINOISSIER and ROQUE have recorded, in *L'Union Médicale*, experiments which they have carried out upon nineteen persons in good health or with disorders of the digestive apparatus. They gave to these patients cane sugar, glucose and lactose in varying quantities, but always in large amounts, so much as to indicate that the resultant glycosuria was a true overflow or an effort upon the part of the economy to get rid of material which it could not utilize. In 29 per cent. of the cases 750 grains of cane sugar produced saccharinuria, and in all of the cases glycosuria ensued when as much as 5,200 grains were administered. As a result of their studies they conclude, as have a number of others before them, that for each person and for each sugar there is an individual co-efficient of utilization, and they have pointed out the fact that as the ingestion of comparatively small quantities of sugar may be followed by glycosuria we should be cautious in making a diagnosis of pathologic glycosuria until we are sure that the sugar in the urine is not an evidence of what might be called overflow. In the *Berliner Klinische Wochenschrift*, for November, 1896, STRUEMPELL, it will be remembered, made a contribution to the study of dietetic glycosuria in which he points out that if the amount of carbohydrate food is sufficiently great, and oxidation processes are imperfect, this failure in oxidation will result in sugar appearing in the urine, and in chronic alcoholics particularly those who drink an excessive quantity of beer, he found that this dietetic glycosuria was readily produced. It is evident, therefore, that we must have in association with glucose in the urine the characteristic symptom group of true diabetes mellitus before we can make a diagnosis of this disease. There must be a tendency to loss of weight, showing that the overflow is in reality a leak. There must be excessive thirst, itching of the skin, excessive hunger, indicating that there is an attempt on the part of the system to make up for the leak, and a tendency to polyuria before the physician has a right to make a definite diagnosis that the patient is suffering from diabetes mellitus. In other words, the presence of sugar in the urine does not indicate diabetes mellitus with its resulting pathologic changes throughout the body, is not a condition requiring so grave a prognosis and is one which simply requires watching by the physician, and avoidance on the part of the patient of excessive quantities of those foodstuffs which the glycosuria indicates he can not readily deal with.

Recently a writer in one of the medical journals of the Atlantic coast, endeavored to prove, first, that gly-

cosuria is pathognomonic of diabetes, and second, that glycosuria would inevitably follow the taking of glucose into the stomach, since under these circumstances it would be absorbed directly into the general circulation without passing to the liver and as a result the patient would become diabetic. Such a woful ignorance of the distribution of the portal vein and of the fact that substances absorbed from the stomach go to the liver through the portal vein in the same manner as do substances absorbed from the intestine, seems to us inexplicable, and the assertion that the entrance of sugar into the stomach would result in diabetes because of its direct absorption, if true, would render most of the population of the United States sufferers from this disease; for, by this theory the conversion of starch into sugar will always result in diabetes, or at least in glycosuria, unless this conversion takes place in the small intestine. Such statements made by one who pretends to a knowledge of the physiology of digestion and assimilation in connection with the carbohydrates would not be worthy of attention were it not that they were presented to the medical profession in a journal of high repute and may serve to befog the minds of those who without careful thought accept views as stated by a writer without carefully analysing the physiologic and anatomic basis for his dogmatic assertions.

SUBPERIOSTEAL HEMATOMA IN RICKETS.

Under this name, and under the name of MÖLLER-BARLOW'S disease, a condition has been described in which a hemorrhagic effusion takes place under the periosteum, which is quite rare, but nevertheless interesting. Six cases of this rare disease have recently been recorded by BRUN and RENAULT, of Paris, in *La Presse Médicale*, Jan. 12, 1898. These six cases were observed in the Hospital for Children's Diseases during the past two years. The first case was that of a girl of three months. The father and mother were healthy, but a younger brother had died in convulsions. The child was born at term after a normal labor and had been nursed for six months. It was brought to the Hospital because of the swelling of the right thigh. The general appearance of the child was good. The fontanelle, however, was wide open, but there was no cranial tabes, no thoracic deformity and the belly was not particularly bulging; perspiration was, however, abundant and the skin pale. The liver and spleen were not hypertrophied nor were there any signs of syphilis. The right thigh was greatly increased in size, the swelling being that of a large orange surrounding the femur and commencing just above the knee. The tumor was hard, but the subcutaneous tissues were movable. The skin had its normal color. There was no crepitation. Palpitation of the femur did not reveal much pain. There were no lesions of the gums, no cutaneous hemorrhages and no

ocular symptoms, nor was there any fever. The child did not suffer from either constipation, vomiting or diarrhea and the lungs were clear. In the absence of joint phenomena it was evident that the case was not one of osteomyelitis, and fracture was readily excluded by the absence of crepitation and abnormal mobility and by the size of the tumor. Syphilis and osteosarcoma were also excluded. BRUN and RENAULT also decided on a preliminary puncture and then found that the contents of the tumor was pure blood. The child was placed upon antisyphilitic treatment, without result, and shortly afterward suffered from measles, but recovered from the acute attack only to succumb to a bronchopneumonia.

At the autopsy the ordinary lesions of rickets were discovered and the right femur was found surrounded by a considerable effusion and was enlarged with a somewhat spongy material.

The second presented symptoms very similar in character. It occurred in a child of ten months.

The third case occurred in a child of twenty-eight months. The swelling was found in the left thigh, which was also painful. There was, however, no vomiting, nor diarrhea. The general condition was pretty good, although the skin was pale and the belly was enlarged. There were no subcutaneous hemorrhages. There were, however, other evidences of rickets which were quite marked, such as deformity of the long bones.

The other cases occurred in children aged fifteen months and two years. In one of them an examination by means of the radioscope failed to show any distinct abnormality about the femur, although it was practically impossible to keep the child quiet long enough for a proper radiographic picture to be taken.

In the sixth case, also that of a child of two years, a successful radiographic picture presented a femur apparently perfectly normal, without any deformity or fracture, the X rays passing readily through the effusion. For this reason the radiographic picture was without result.

These cases are, we think, of interest in that they might so readily mislead one into the view that there had been a traumatism, or that an osteomyelitis was developing: or again, that an osteosarcoma or a osteotuberculosis was present. Even advanced syphilitic disease might be thought to be the cause of the lesion. It is only when we remember the studies which have been made by MÖLLER, by BARLOW and by CHEADLE, who so well describe acute rickets manifesting itself in hemorrhagic tendencies, and scorbutus in infants, that such cases would appear to us to be not due to a grave cause, but to a diathetic condition generally known as rhachitis. The sudden onset of the malady might often mislead us into the belief that there had been severe traumatism. As pointed out by BARLOW and others, it is entirely possible for the periosteal

hemorrhage to occur in other parts than the surfaces of the long bones, and in MÖLLER'S cases it occurred in the neighborhood of the orbit. The subperiosteal effusion gave the appearance of great swelling and ecchymosis of the forehead.

HIRSCHPRUNG, who has seen ten cases, found the lesions distributed as follows: On one femur in three cases; on both tibias in two cases: on the left tibia and right humerus, one case; on both tibias and one humerus, one case; on the right scapula, left femur and right tibia, one case; on both tibias and both forearms and extremities, one case; on the right humerus and right forearm in one case.

In the paper by BRUN and RENAULT, which we have quoted, the hemorrhage occurred five times in the femur and once in the humerus. It is a noteworthy fact that these subperiosteal hemorrhages are not usually accompanied by hemorrhages into other organs, but such hemorrhages may occur. In four of HIRSCHPRUNG'S cases there were swelling and redness of the gums, but no ecchymosis, and in the six cases reported by BRUN and RENAULT there were no lesions of the gums. Fever in such cases is usually very moderate and a cure usually results. Pain is also not severe. As the swelling is absorbed the movements of the limb becomes more easily performed and finally recovery takes place. Death is usually very rare, unless there be in association with the attack general purpura, albuminuria or bronchopneumonia.

From a study of their six cases BRUN and RENAULT conclude that the disease is a different one from that which is usually considered as scorbutus or acute rickets. The chief and typical symptom is the subperiosteal hematoma, which is without the accompaniment of other symptoms. The hematoma appears without there being any fracture, complete or incomplete, to the bone, although in rare instances some traumatism may be responsible for it.

Predisposing influences, such as a tendency to hemorrhagic diathesis, or scorbutus, may, of course, lead to the development of such hematomata.

SOME PUZZLING FACTS OF IMMUNITY.

Our knowledge of the causes of disease has unquestionably been greatly enlarged by the bacteriologic investigations of the past fifteen or twenty years, and we are constantly acquiring new information that is of the highest theoretical and practical importance. With the positive data, however, thus gained, there are others the signification of which is a puzzling problem, and that sometimes appear to contradict or overthrow the conclusions deduced from what have appeared to be well established pathologic acquisitions. Thus we find that even the more virulent pathogenic microbes do not always behave in the same way and there still remains a certain degree of indefiniteness in our knowledge of the behavior of any germ

disease analogous to if not quite as extensive as that which formerly existed when bacteria were unknown and the causes of contagious and infectious diseases were yet an unsolved mystery. The natural history of these lowest forms of plant life has not been by any means thoroughly worked out, and as pathologists we are perhaps not exactly on the right road to this result. We do not study them as naturalists; our aim is to follow them in their pathologic relations to learn to use their microscopic characters and behavior in cultures for diagnostic purposes, and we do not apply to these investigations the critical observation of the systematic naturalist who studies the life history and development with a taxonomic skill derived from long experience and sharpened by competition and criticism. The specific characters of a simple rod or dot of matter visible only under a high-powered lens are not very marked or numerous, nor are they very adequately supplemented by their behavior to coloring reagents or in coloring cultures. These facts leave us in a certain condition of uncertainty in regard to many often mooted points and there are at least a few so-called pathogenic bacteria that tried by the ordinary laws of evidence might escape on the ground of a reasonable doubt from conviction for the homicides of which they are accused, and for which according to accepted pathologic usage they are considered entirely responsible.

The bio-chemistry of the products of these organisms is also rich in puzzling problems and the whole subject of immunity is a riddle the solution of which seems still very far in the future, if indeed it is ever to be satisfactorily solved. No generally applicable and satisfactory law of immunity has yet been formulated, or at least the exceptions are too numerous to exactly prove the rule. In a general way we may say perhaps that custom and familiarity with organic or infective toxins seem to breed a pathologic contempt, but this is only partially true. Why scarlatina for example, which was reckoned as a trivial affection in SYDENHAM'S time, should still exist now for years at a time one of the most fatal of children's maladies and then again apparently and without reason taking on a milder type, while always with us in one form or the other, is not very clear, and other similar instances might easily be adduced. We know as little the laws that govern this apparently capricious behavior of pathogenic organisms in the human subject as we know the reasons why certain other warm blooded animals are habitually immune to their maleficent action, so fatal often to our own species.

One of the most striking examples of apparent immunity to an especially virulent pathogenic microbe has been lately reported by two Italian observers, MONTESANO and MONTESSORI, in the *Centralblatt f. Bacteriologie* of December 22, last. They were studying the bacteriologic contents of the cerebro-rachidian

fluid, and made the surprising discovery of the existence of NICOLAÏER's tetanus bacillus in the fluid drawn by lumbar puncture from a paretic dement in the later stages of paresis. According to the report given, the puncture was made with due antiseptic and aseptic precautions, and the immediate injection into a guinea pig of the derived fluid caused death from tetanus in five days. Similar results followed injections from pure and mixed cultures from the fluid.

In order to test the observation, a second lumbar puncture was made four weeks after the first one and the same results were obtained. After the patient's death, which occurred in the natural course of his disorder some weeks later, postmortem cultures of the cerebro-spinal fluid made by MINGAZZINI revealed the same organisms as did the punctures during life, non-virulent streptococci and tetanus bacilli, together with another form supposed to be *bacillus oleaceus*.

This observation, which we are not justified in discrediting *a priori*, almost completely overturns our generally accepted notions as to the pathogenic virulence of the tetanus bacillus. If an organism that, elaborating its toxin in a distant peripheral wound, can poison the whole central nervous system and render it directly toxic to other individuals, can live and flourish in the cerebro-spinal fluid itself, without apparent injury to its host but still preserving all its virulence for control experiments, we shall have to remodel some of our ideas as to its invariably pathogenic qualities to a very considerable extent. Is it possible to suppose that there is a rival toxin in paresis that immunizes the paretic to that of NICOLAÏER's bacillus? The Italian investigators suggest that the existence of this organism in their patient may have had some connection with the congestive and epileptic attacks, but this seems on the whole a somewhat gratuitous assumption, as the case does not appear to have been especially remarkable in this respect. The cerebro-spinal fluid appears to have furnished here a specially favorable culture medium, with conditions as regards temperature, association with other organisms, etc., altogether suitable to the development of the pathogenic peculiarities of the germ and yet the patient, so far as could be shown, was not materially worse for their presence.

The report, as far as it goes, adds another puzzling fact to the literature of immunity, and one that is not quite as readily disposed of or accounted for as some others of its kind. To the well known facts that men can exist in apparent health with diphtheria bacilli in their throats, pneumococci in the blood, tubercle bacilli constantly in the lungs and digestive tracts, and other pathogenic species distributed throughout the organism, we have now to add, according to this latest evidence, that under certain conditions they can also carry the tetanus bacillus and toxins in their nerve centers, without there producing their charac-

teristic lethal effects. The conclusion from all the data is that immunity is elastic, that we have by no means yet learned its limits and that in the whole subject of poisoning by bacteria and their products there are likely to be revealed many things as yet not dreamed of in our philosophy. To accept this as true does not in any way detract from the importance and value of the genuine acquisition to our knowledge of the pathologic relation of these organisms. The facts of infection and its possibilities and of the means of preventing them are too well established to be overthrown. But it may be that in these anomalous discoveries and observations we may find something yet that will reveal new methods of protection against even those agencies that seem at present most formidable.

SURGERY AS A SPECIALTY.

At present there is a delusive kind of fascination in making surgery a special study. Most of the recent graduates aspire to eminence in this field. The apparent certainty of diagnoses, treatment and results seem so clear and tangible, that the practice is sought for as the shortest road to fame and fortune. In a graduating class of one hundred and forty, sixty expressed their intention of pursuing surgery as a specialty. It is the common observation that among the large number of well trained surgeons, who are also teachers in large cities, few ever attain more than a narrow local reputation. Fewer still ever do any original work, or advance the boundaries of the known. Our readers will recall many very active surgeons who have an immense experience and practice, who have never published a new fact or new method of procedure. They will also recall a number of volumes which are absolutely without any new facts, and in some cases are weaker and more feeble statements of truths already well known. It was a source of wonderment to many persons that a most accomplished surgeon and teacher never contributed a single new fact to surgery, although he wrote well and voluminously. The literal explanation is that surgeons are born not made, and no amount of training and experience can make one who will do original advanced work unless he has some natural fitness for it.

Modern surgery calls more and more for first-class mechanical talent; it calls for natural machinists with a strong mathematical brain, full of resources and capable of using the present means to the fullest extent. Such men are resourceful, inventive and reasoning; their observation and judgment are clear and independent. Every great surgeon would have made a leading mechanic or inventor, or great business operator, and every great surgeon is original in his work although it may be confined to small details. The mere mechanics of surgery may be acquired in a

degree by nearly every one, but a knowledge of the higher mechanics of the chemico-physiologic work of the organism can only be understood by a natural born inventor and mechanic. The dexterity of operating is not comparable with the reason and judgment of when and how to do it. A noted New York surgeon while riding in the country broke a wheel of his carriage; he soon repaired it with such skill that he was able to continue on his journey as if nothing had happened. Another surgeon broke his carriage in the same way and left it, continuing his journey in another vehicle. One had the mechanic sense developed, the other was without it.

Every physician should be able to act in emergency cases, but the man who aspires to be a specialist in this field should have strongly marked inventive genius. This specialty is a very poor field of practice to one who is not especially adapted for it.

Unfortunately in medicine, as in other professions, there are many ill trained and ill adapted persons for the work required, but the aspirant for surgical honors without natural mechanical and surgical capacity, is literally more unfortunate than others.

CORRESPONDENCE.

The Free Medical and Surgical Treatment of the Well-to-do in Michigan University.

ANN ARBOR, MICH., March 2, 1898.

To the Editor:—I do not know what authority you have for the editorial that appeared in your issue of February 26, under the above heading. This editorial contains some truth mixed with much error, and you will please allow me to separate the truth from the error. You state: "Since their establishment, the Clinic and University Hospital at Ann Arbor have, as a rule, treated all who applied. Occasionally a particular professor would object to treating a notoriously rich person, but no rule has been adopted. Moved, doubtless, by the protests of the profession and their own sense of equity, the medical faculty requested the Board of Regents, at a late meeting, to exclude all well-to-do people seeking admission to the university hospital. The Board has the matter under consideration. It is reported in the public press that the majority are opposed to such exclusion of the rich. They hold that the hospital is for teaching students of the Medical Department, and that a millionaire makes just as good a subject for teaching as a pauper; that he pays taxes to the support of the hospital, and so has a right to the free services of the university hospital staff."

The truth of the matter is that in 1883 the Board of Regents adopted a by-law authorizing the faculty to exclude from the hospital and clinic all patients who were able to pay for medical services. I have no doubt that some people have imposed upon the faculty, but this rule has been adhered to as closely as possible and is still in force today. A few months ago, a man known to have a sufficiency of this world's goods to enable him to pay a fair doctor's bill, applied for admission to the hospital. In accordance with the rule already mentioned, he was refused admission. He appealed to the Board of Regents on the ground that he was a tax-payer and helped to support the University and the hospital. The Board of Regents

ignored his appeal and refused to make any change in the rule adopted in 1883 and in effect since that time.

In the editorial you speak of a doctor living in western Michigan who for years has been able to keep his cases of cataract only by figuring out the railway fare to and from Ann Arbor and the cost of two weeks board at three dollars per week, and by offering to do the operation for the resulting sum. Please allow me, through your columns, to inform this physician that he can increase his price. The cheapest board in university hospital is \$5 per week, and when the individual occupies a room alone, the charge is \$9 per week. I am sorry that this physician has been losing, as a result of his figuring out the cost of an operation at the University. Furthermore, if any doctor in the State of Michigan will inform the medical faculty that any individual coming to the hospital is able to pay a reasonable fee for the operation to be performed, such applicant will be refused admission to the hospital. Of course, it is quite impossible for the medical faculty to always ascertain the financial standing of patients applying for admission, but both the faculty and the regents have always endeavored, and I think that I may say always will endeavor, to act for the best interests of the medical profession. It would be very unwise for the Board of Regents to educate and graduate physicians and then take from them the means by which they are to make their living.

Respectfully,

V. C. VAUGHAN, M.D., *Dean.*

"Oxytuberculin."

SAN FRANCISCO, CAL., Feb. 24, 1898.

To the Editor:—In the JOURNAL of February 5 (p. 336) it is noted that the Audiffred Prize of 100,000 francs for the cure of consumption was not granted to me by the French Academy of Medicine on account of not being sufficiently established by experiments upon animals. I was very much surprised to find my name mentioned in this connection at all, as I had neither applied for a prize, nor did I know of its existence. My work, together, with an official translation, had been presented by the minister of foreign affairs to the Academy and to the Pasteur Institute of Paris for investigation, and it is pleasant to me that it was favorably commented upon by the Academy.

It was and is my desire that the doctrine of the curative effect of oxidized toxins should be most skeptically investigated in order that its truth should be established by others as it has been by me. As stated in the presentation to Cooper Medical College (published in the JOURNAL of February 5), I had not entered at all upon the field of animal experimentation, but had limited my work entirely to the clinical and bacteriologic sphere, in both of which the evidence was indubitable. In the JOURNAL of February 19 a Dr. Smith criticises the evidence presented in rather an acrimonious manner. His feeling toward Cooper Medical College may be explained by the fact that he has had an unpleasant correspondence with another member of the faculty, which assumed such a character that Dr. Smith's last letter to the gentleman was returned to him unopened. I am not acquainted with Dr. Smith, who lives in a small village some fifty miles from here, and he certainly knows nothing whatever about my cases. He has had some unpleasantness with a medical gentleman, who is using oxytuberculin with most excellent success, in Santa Clara.

With regard to the cases of cured and improved tuberculosis as stated in my published lecture, I have reported a large number that had been examined before, during and after treatment by various medical men, and the sputum slides were presented in evidence before the investigating committee, who likewise examined my culture experiments in the laboratory from time to time. The hygienic condition of the patients treated were absolutely unchanged, nor were other remedial agencies employed. A number of the cases were treated at our City and

County Hospital, where the conditions are notably unfavorable; so bad, indeed, that the city will shortly be compelled to tear down the buildings and erect new ones. The patients are kept on the poorest possible diet, thirteen cents per day being allowed for feeding. These cases (among them the cured miliary tuberculosis reported), have been watched by physicians and students, so that there can be no doubt of the facts.

I am sorry that any personal feeling should actuate discussion upon so serious a subject as a cure for tuberculosis, for there should be no mud-throwing in the temple of science.

It gives me pleasure to state that a large number of medical men throughout the United States have confirmed my favorable statements, in spite of the fact that most of the cases reported have been far advanced. I have distinctly stated that I made claims for the curative action of oxytuberculin only in the early stages of tuberculosis, where it will certainly be found to be a specific. Respectfully,

433 Geary Street.

J. O. HIRSCHFELDER, M.D.

Appendicitis.

NEW YORK CITY, March 1, 1898.

To the Editor:—I will undertake to refute the arguments of any correspondents who maintain that we should not make it a rule to operate upon cases of appendicitis as soon as the diagnosis is made. The matter is one of grave importance because the deaths from appendicitis in the United States alone have been estimated, from safe data, to amount to more than fifty thousand annually. Physicians carry into practice the ideas which they believe to be right, and patients are practically helpless in the matter because they must abide by the decisions of the physicians in whom they have placed confidence. Some physicians are wrong; some are right. The ones who are wrong treat as many patients as the ones who are right. Patients do not know the difference and they do not realize that deaths from appendicitis are usually unnecessary deaths. Most of the physicians who are in the wrong on appendicitis questions are more than willing to be set right, but they are apt to become confused unless they are surrounded by an environment which allows them to take judicial positions, instead of the positions of advocates.

I will be brief in my part of discussions, and correspondents can state their points briefly, so that not much space will be required in the JOURNAL. The editor can finally sum up the evidence and can render an important decision upon the subject which directly involves the lives of thousands of individuals.

My proposition is that we must make it a rule to subject our appendicitis patients to operation as soon as a diagnosis has been made. The reasons for my proposition are:

1. No physician will ever be able to prejudicate upon the extent of bacterial ravages in any given case of appendicitis.
2. If we wait to see whether a mild case is to remain a mild case, the cases that are not mild become complicated cases before operation is done and we then have an unnecessary death rate, an unnecessary suffering rate, an unnecessary loss of time rate.
3. Operations properly performed at the outset of infective appendicitis have a smaller loss of time rate, a smaller suffering rate and a smaller death rate than can be given by any sort of medical treatment.
4. Operations performed properly by the surgeon when bacteria are causing progressive destruction of tissues outside of the appendix, are less dangerous than the operations that the bacteria perform.
5. Operations performed properly when patients are apparently convalescing from acute appendicitis, avoid the surprises that appear in the form of infective phlebitis, portal embolism and other metastatic complications which are so often observed by those of us who are engaged in appendicitis work.

6. Operations performed properly, in the interval between attacks of appendicitis, give results similar to those performed in the early infection stage.

I believe that it will be an easy matter to refute any arguments to the contrary of my proposition, but I would like very much to have the matter discussed very promptly because patients are hourly dying unnecessarily from appendicitis, and and it is high time that a preventable death rate be prevented.

49 West Thirty-ninth St.

ROBERT T. MORRIS, M.D.

Staphylococcus Infection Not Tuberculosis.

OCONOMOWOC, WIS., Feb. 28, 1898.

To the Editor:—Miss B. applied for treatment at Sanatorium Waldheim, Nov. 21, 1897, on account of a hacking cough, bloody expectoration, general emaciation and night sweats. The patient is single, a servant, 21 years of age. Both parents are dead; father died of tuberculosis; cause of mother's death unknown. Patient says she has always been well up to May, 1897, when she took a severe cold, causing a cough which lasted through the summer and increased toward autumn. She weighs 104 pounds, is anemic, cheeks slightly flushed and gives the impression of one in the second stage of tuberculosis. She coughs mostly toward night, expectorates (with difficulty) a small amount of blood-stained sputum and often vomits after a severe attack of coughing. She has anorexia, night sweats, and does not sleep well. Expansion of chest is fair, with slight dullness over both apices, harsh breathing and some hoarseness. Pulse 100 and an evening temperature of 100 to 101 degrees. I had not much doubt that the case was one of tuberculosis and that tubercle bacilli would be found in the sputum.

A tonic mixture of muriatic acid, quinin, etc., was prescribed to create an appetite and improve digestion, cold packs ordered to be given late in the afternoon daily and the diet was strictly attended to, but the patient's condition, especially the cough, grew rather worse during the first week. In the meantime Dr. Folsom made several microscopic examinations of the sputum without finding any tubercle bacilli, only staphylococci and a few other bacteria being found. A larger quantity of sputum was now collected and centrifuged, after which we obtained several slides of almost a pure culture of staphylococci in endless numbers, but not tubercle bacilli. The cold packs, a yet more nourishing and substantial diet, and the tonic mixture were continued, and in addition, general massage and moderate exercise ordered. There was given besides this, alternate inhalations of a 1 per cent. solution of argenti lactas and a 5 per cent. solution of guaiacol: the first solution A. M. and the last P. M., for five minutes by means of a multiple comminutor (in my mind the only inhaler which is efficacious). Soon the improvement in the condition of the patient was apparent. At the end of the second week she had very little evening temperature, had a better appetite, complained much less and had gained three pounds in weight.

The improvement continued uninterrupted until the end of the fourth week when she was discharged practically well. Had no cough nor expectoration, natural respiratory murmur, no temperature, a normal pulse and general feeling of well being. Her weight when discharged was 114 pounds. She has reported a few times since, always being well and gaining in weight, weighing now over 120 pounds.

I wish to put this case on record as an example of the importance of a microscopic examination of the sputum of such patients. It is quite possible, had the ulcerative bronchitis and staphylococcus infection not been detected, that this patient would have eventually, and probably during the winter, succumbed, with or without an additional infection of the tubercle bacillus, which later would have found a properly prepared soil for its implantation.

J. H. VOJE, M.D.

The Manufacture of Antitoxins.

CHICAGO, ILL., March 2, 1898.

To the Editor:—I have just read the paragraph entitled "The New York City Board of Health" that appeared on page 506 of your issue of February 26.

Permit me to point out that ever since January, 1895, diphtheria antitoxin . . . could have been purchased in New York City at a cost never exceeding \$2 per vial of 10 c.c., representing 1500 units, or approximately \$6 per ounce. The pretension, therefore, of the Board of Health, that the cost of diphtheria antitoxin at the drug store was \$12 per ounce, and therefore excessive, is absolutely without foundation. Please note that diphtheria antitoxin . . . is recognized all over the country as a standard product. Practically none has been sold for consumption in New York City itself owing to the competition of the Board of Health. But that does not alter the fact that our diphtheria antitoxin has always been obtainable in New York City at the price named, and in fresh and serviceable condition. The New York City Board of Health must be in a very precarious condition to resort to such unfortunate misstatements in its attempt to retain its power to manufacture medicinal or other preparations in competition with private parties. I do not believe that the spirit of paternalism which now pervades certain public bodies is a correct echo of public sentiment, and appearances indicate that it will be nipped in the bud. A sign of the times is the reduction by the Senate, to \$25,000, of the appropriation of \$100,000 applied for by the Department of Agriculture for the manufacture and supply of hog cholera vaccine, the reduced appropriation being made with the stipulation that the serum manufactured should be utilized exclusively for official experiments, and none of it should be gratuitously distributed. We enclose herewith copy of an extract taken from the *Oil, Paint and Drug Reporter* of New York City, which may possibly be of interest to you.

Yours very truly,
HAROLD SORBY,
Manager Pasteur Vaccine Co.

THE SENATE DISAPPROVES THE DISTRIBUTION OF SERUM.

Readers of the *Reporter* will be pleased to learn that the strong protests made by the manufacturers of pharmaceutical preparations and others against the proposition of the Secretary of Agriculture to spend \$100,000 in the manufacture and gratuitous distribution of 2,000,000 doses of hog serum has been disapproved by the Senate. Unless the House fails to agree with the Senate's action, which is not likely, this effort at paternalism will come to naught.

The Secretary of Agriculture has been making a series of experiments through the Bureau of Animal Industry which has resulted in demonstrating to the satisfaction of the experts that a serum can be produced which is very effective against hog cholera. The Bureau officials became so enthusiastic over the results achieved that they induced the Secretary to appear before the Senate Committee on Appropriations, and request an appropriation of \$100,000 for the manufacture of serum to be gratuitously distributed through the medium of the agricultural experiment stations and colleges. The editorial comment upon this action which appeared in the *Reporter* last week greatly stimulated protests against this action, and such a flood of remonstrances reached the chairman of the committee and his colleagues in the Senate as to convince the framers of the agricultural appropriation bill that public sentiment was strongly opposed to the Secretary's project. After several conferences Senator Allison, who is chairman of the Appropriation Committee, decided to reduce the sum requested by the Secretary to \$25,000, and to concede it only with the distinct understanding that but a limited quantity of the serum should be manufactured and that it should be utilized exclusively for official experiments and none of it should be gratuitously distributed.

The officials of the Bureau of Animal Industry are greatly disappointed at the failure of their plan to distribute the serum widely, but Senator Allison is confident that the real function of the Bureau, which is to determine by experiment the efficacy of remedies for animal diseases, will not be circumscribed as the result of the reduction, while at the same time the Department will be relieved of the criticisms which have been directed against a proposed invasion of a legitimate field of private enterprise.

The victory of the trade is of far greater significance than the mere prevention of the gratuitous distribution of hog serum. It is in effect a recognition on the part of the Senate of the impropriety of the Government's entering into competition with private firms in any line of industry, and there is no doubt that the precedent thus established will be of great value to the business community hereafter.—(From *Oil, Paint and Drug Reporter*, Feb. 14, 1898.)

Opinions Differ.

MINNEAPOLIS, MINN., Feb. 21, 1898.

To the Editor:—I notice in the *JOURNAL* of January 15 what I consider a very unfair criticism of the excellent work on surgical diagnosis and treatment by J. W. MacDonald, M.D.

1. The reviewer states that "the book might be compressed into two-thirds its size" and that "the author has lost the art of condensation." In the face of the fact that the author is a speaker and a writer of rare ability both on medical and other subjects, the statement raises a question in the mind of the reader as to whether the assertion is not biased by selfish motives.

2. That "it is foggy in regard to tumors." If there is any fog about tumors it must exist in the mind of the reviewer, as many able authors entertain the same views as set forth in this work.

3. That "gas and the electric headlight has superseded the student's lamp as a means of examining the larynx." The idea of the student's lamp may appear ridiculous to a resident of Chicago but there are doctors outside of the Windy City who are not prejudiced by the lantern and cow who are where electricity and gas are not obtainable.

4. The typographic error on page 579 in regard to the word Adams is admitted. The author is not the only one suffering from a "deviated" letter, as I notice the reviewer has a new way of spelling W. B. Saunders.

A MEMBER OF THE ASSOCIATION.

A Prescription Corrected.

PHILADELPHIA, PA., March 3, 1898.

To the Editor:—By an inadvertency an error has found its way into the report of my clinical lecture published in the *JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION* for Feb. 26, 1898. On page 464, in the second column, the second prescription should read as follows:

R *Pepsini glyceriti* ʒv. 147 85
Acidi hydrochlorici diluti m. cc. 12 32
Sig.—Two teaspoonfuls after each meal.

In reading the proof furnished me that portion which contained the above prescription was missing. I have been informed by your printer that two galley slips had stuck together and that the prescription, together with the adjoining portion of text was concealed.

JOHN V. SHOEMAKER, M.D.

Wants Statistics of Homeopathy.

CHICAGO, March 1, 1898.

To the Editor:—It would be interesting and valuable to know, according to reliable statistics, the number of homeopathic physicians, colleges and hospitals in the United States at the present time as compared to the number ten, twenty and thirty years ago.

If it seems wise to the editor, I think a statement of such statistics would be very generally appreciated.

Very respectfully, R. S. PORTER, M.D.

ASSOCIATION NEWS.

Prospective Attendance at the Denver Meeting.

DENVER, COL., Feb. 28, 1898.

To the Editor:—I send you this communication in the way of a preliminary report relative to the prospective attendance

at the forthcoming Denver Meeting, thinking that it may be of interest to the members of the AMERICAN MEDICAL ASSOCIATION. As Chairman of the Local Committee upon State Medical Societies, I have opened a correspondence with the officers of all the State societies with a view to awakening a degree of interest, thereby securing as large and enthusiastic delegations as possible, and to ascertaining in reply an approximate estimate of the probable attendance from each State. The answers thus far received have been, upon the whole, extremely gratifying, and from the assurances contained indicate the development of a decided general interest with a growing spirit of enthusiasm relative to the next annual meeting. The exhibition of this feeling may be reasonably expected to result in a large and representative gathering of medical men in Denver next June. That the meeting will be a brilliant success in point of numbers and character of attendance is already practically assured by the expressions received from all parts of the country. The larger number of replies have been necessarily of a purely general nature. The fact that a majority of the State societies do not hold their annual meetings until April or May renders it impossible for their officers to form any adequate estimate as to the size of the delegations from the respective States. In but few instances have delegates been appointed as yet. Those whose names I have been able to secure have been corresponded with. Some have replied, signifying their intention to come and bring others. Nearly all the officers of the various State societies are taking energetic measures to create an active interest among their fellows, and predict in behalf of their local organizations a generous representation. The names of the many delegates will be furnished me as soon as the appointments have been made, and they will be communicated at once. Thus far general estimates have been received from thirteen States, representing a total of 618. While from the remaining States no official information has been received upon which to base provisional opinions as to the relative size of delegations, still sufficient data of a general nature have been secured to justify the conclusion that the estimate quoted for the thirteen States will be a fair proportionate index of the whole. From this it seems safe to assume that the attendance at the next meeting will equal that of any previous year. If the voluntary expressions of those in authority in the various States may be considered as reflecting to any degree the sentiments of the individual members it is apparent that a strong feeling of interest and hearty enthusiasm is already aroused. Did space permit I would quote brief extracts from the many letters received, evincing the most earnest sympathy and active co-operation. The earnest work undertaken in some of the societies should stimulate all to renewed efforts toward insuring the success of the next annual meeting. Very sincerely yours,

S. G. BONNEY, M.D.

NECROLOGY.

THOMAS B. BAILEY, M.D., appointed to the U. S. Navy from New York in 1889, and made a Passed Assistant Surgeon in 1892, died in Washington, D. C., February 24, aged 34 years. He had been on the China Station but was lately ordered home and to duty at the Washington Navy Yard.

WILLIAM S. TORREY, M.D., New York University, 1884, died in Brooklyn, N. Y., after a long illness, in his 36th year, on March 4. His remains were interred at his former home in Honesdale, Pa.

JOHN C. SHERMAN, M.D., in charge of the U. S. Marine Hospital at Ogdensburg, N. Y., died in New York city March 2, aged 48 years.

DEATHS ABROAD.—Dr. Jennie Taylor Gordon, wife of a missionary in Africa and niece of Bishop William Taylor of the M. E. Church, died at Malange Angola, West Africa, Decem-

ber 29. She was known as "Dr. Jennie" in the foreign missions and during her long service abroad acquired an enviable reputation for skill. Her parents are residents of Mechanicsburg, Pa.

JAMES J. STEPHENS, M.D., College of Physicians and Surgeons, New York, 1846, died from apoplexy at his home in Tappan, N. Y., March 3, in his 75th year. He was born in New York city but came to Tappan forty-three years ago and for forty of these he was owner of the Major André prison house, from which he religiously excluded the public. After this structure was blown down in part on November 2 last, the next owner rebuilt it and made its inspection free. Many stories are told of Dr. Stephens' skill and eccentricity.

WILEY H. WILSON, M.D., Lake Geneva, Wis., February 27, of cerebral hemorrhage. He was born at La Grange, Ga., Jan. 6, 1812, and when the war broke out he was a student at the University of Athens, which he left at the age of 19 to join the Southern army in West Virginia, where he served on General Rhodes' staff in Stonewall Jackson's brigade. He was with General Lee at the surrender at Appomattox courthouse. After the war he studied medicine in Louisville, Ky. In 1880 he moved to Chicago, where he practiced his profession five years, and then moved to Lake Geneva.

ROBERT A. WHEATON, M.D., St. Paul, Minn., February 25, aged 30 years. The Doctor was graduated from Harvard in 1889, clinical instructor in surgery at the University of Minnesota, a member of the AMERICAN MEDICAL ASSOCIATION, the Minnesota State Medical Society, Massachusetts Medical Society and Association of Military Surgeons of the National Guard.

THOMAS JEFFERSON MOORE, M.D., Richmond, Va., February 24, aged 58 years. Dr. Moore was a native of North Carolina, served as a member of the Senate of that State, was for four years a member of the Virginia State Medical Examining Board, a member of the AMERICAN MEDICAL ASSOCIATION and honorary member of the North Carolina Medical Society, and filled the chair of clinical medicine in the University College of Medicine at Richmond.

FRANCIS G. HENRY, M.D., Kansas City, Mo., February 26. He was born in Paris, Ky., in 1828, and about 1860 moved to Missouri. He entered the Confederate army and accompanied Price in his first raid. He also served under General Shelby. During Governor Crittenden's administration, Dr. Henry was appointed superintendent of the asylum for criminal insane at Fulton, Mo., he being the first to hold that position.

JOHN PARKER MAYNARD, M.D., Harvard, 1848, of Dedham, Mass., February 26, aged 72 years. He was born in Boston, Mass., was a graduate of Yale and in 1847 the discoverer of collodion, which he soon utilized in surgery.

JOHN YALE, M.D., Yale 1841, died in Beloit, Kan., February 26. He was a descendant of the founder of Yale College and born in New Hartford, Conn., April 2, 1820. Most of his life was passed in Ware, Mass.

SAMUEL AUGDEN HILLS, M.D., Yale 1846, died at his residence in New York city after a long illness, February 26, aged 76 years. During his professional life he was an apothecary, a coroner, lumber merchant and a realty investor, having accumulated considerable wealth.

A. RUSSELL STRACHAN, M.D., died at the St. Cloud Hotel, New York city, March 1, as the result of injuries received a week before in an effort to save a woman and child from being run over by a Broadway cable car. Both were rescued. He however thought but little of his hurt and did not immediately take to his bed. He was born in Scotland, was graduated from the Victoria University, Ontario, 1861, and long ago was connected with Luke's Hospital New York. An obituary note credits him with being the author of various medical works and of many magazine contributions.

CLARENCE LEWIS, M.D., aged 24 years died in San Francisco,

Cal., February 20.—W. H. Hill, M.D., South Onandago, N. Y., February 26.—William Coe Holmes, M.D., College of Physicians and Surgeons, New York, 1880, died in Waterbury, Conn., February 24.—Hiram Lake, M.D., Holliston, Mass., aged 79 years. W. H. Parkhurst, M.D., Dunbar, Neb., February 25.—Frank W. Root, M.D., Kent, Ohio, February 26.—Samuel D. Seelye, M.D., Montgomery, Ala., February 23.—Alexander Fulton, M.D., Philadelphia, March 1, aged 43 years.

PUBLIC HEALTH.

Proposed "Practical" Medical Legislation for New York State.

Legislation intended to build up the profession's "practical interest" in New York, will not be wanting this year. Free vaccination is to be opposed as inimic to the best (financial) welfare of young medical men. The production of diphtheria antitoxin by official laboratories and its administration free of charge by boards of health, also the attempt officially to repress that "filth disease, pulmonary phthisis," will be legislated against. If the promoters of the "practical interests" bill will also attack the bacterial diagnosis of diphtheria, tuberculosis and typhoid fever in our official laboratories, they will have well done their part toward closing up those branches of work that have hitherto been regarded as objects of congratulation by our more wide-awake boards of health. When New York City began the work which is now proposed to abolish, antitoxin was selling for \$12, but in consequence of the Health Board's production it is now sold for \$1.50. The city's bacteriologic bureau has attracted attention in Berlin, Vienna, England and Scotland, where its method has been copied, as well as in several American cities. An appropriation of \$30,000 a year is made for it by the city, and as much more is realized by the sale of antitoxin and vaccine, which is said to be the purest made in this country. It supplies the city of Chicago. The receipts are applied to the work of the bureau. Last year 9641 visits were made to tuberculous patients, 5000 to disinfect rooms in which patients had died, and 4641 to teach patients not to communicate their disease. There were 968 persons treated with 1400 injections of lymph in 1896, and 1214 were immunized. The number of persons treated last year was 1174, to whom 1600 injections were given and 1714 persons were immunized. Much of this work was done among the poor. If this newly proposed legislation is carried out there must be a very general closing up of important lines of laboratory work. Will the best interests of the medical profession be advanced thereby? One effect we can foresee as possible is that there may be attracted into the medical student class numbers of young men who are looking out for a good "practical" money-making profession; and if this effect shall be produced, some of these legislation promoters may have occasion for sorrow. Is "practical" legislation a two-edged sword?

MISCELLANY.

Carbolized Camphor is strongly recommended for suppurating and inflammatory processes by Ordin, a Russian confrère.—*Cbl. f. Chir.*, November 13.

Surgical Intervention in Perforating Peritonitis from Typhoid Fever.—Monod reports a case in which he performed laparotomy, but the patient died three days later, as the peritonitis continued its ravages. He has had five recover out of thirty-two operated on in these conditions, and considers an operation indicated and justified as a last resort. Routier, Brun and Lejars have each a record of one or two cases thus treated, but none recovered.—*Cbl. f. Chir.*, January 22.

Permeability of the Placenta.—Recent tests with methylene blue to determine the permeability of the placenta, similar to

the tests with the kidneys, resulted in the appearance of the blue in the urine of the infant by the end of an hour and a half, as the minimum. The tests were made on sixteen maternity cases three minutes to twenty-two hours before the expulsion of the fetus. The blue could not be detected in the milk nor in the amniotic fluid.—*Progrès Méd.*, January 22.

A Peculiar Case of Abnormal Genitalia is related by E. Tornu in the *Anales del Circ. med. Argentino* for November. The vagina and uterus were rudimentary; the former without an opening, and one ovary was absent. Menstruation was accomplished through the bladder although no communication between it and the genitalia could be discovered. During menstruation there was absolute anuria for three days, even during the corresponding periods when the menses failed to appear, as happened occasionally.

Experimentation with Combined Coli Bacillus and Pyogenic Cocci in the Etiology of Gastro-Intestinal Fever.—A. M. Coco asserts as the results of research in this line: 1. That the coli bacilli become virulent in the presence of the pyogenic strepto- or staphylococcus. 2. The coli bacilli alone produce no thermic elevation or merely a slight and momentary rise in temperature. 3. The simultaneous ingestion of the coli bacilli and the pyogenic staphylococcus determines an appreciable elevation of the temperature and rapid loss of weight. 4. Cultures of the coli bacilli and pyogenic strepto- or staphylococcus ingested simultaneously, established an intense gastro-intestinal catarrh.—*Gazetta d. Osp. e d. Clin.*, January 23.

Non-diphtheritic Laryngitis Fibriosa.—A case is described by A. Rosenberg in *Therap. Woch.* of December 19, in which a fibrinous growth appears constantly on the larynx, the patient, a man of 67, otherwise in good health. It has persisted a year and a half, in spite of treatment of all kinds. The patches require about a week for their appearance, development and final disappearance, when others appear at other points, all tenaciously adherent, the membrane very much inflamed under and around them. Cicatricial growths in the pharynx indicate old syphilitic infection, denied by the patient.

Recurring Appendicitis. A review of 346 cases of appendicitis treated in the Bathauien Hospital at Berlin shows that in 65 the affection had returned. It recurred once in 37 cases; twice in 10; three times in 6; four times in 1; five times in 1. The interval between the recurrences was one year in 39; two years in 10; three years in 4; four years in 4; five years in 1; seven to ten years in 2, and eight, nine and eleven years in 1. In 5 cases the relapse led to generalized peritonitis. The usual proportion between sexes was observed: 38 children, 211 male adults and 97 female.—*Cbl. f. Chir.*, January 22.

Surgery of the Stomach for Malignant Neoplasms.—C. A. Ewald reports a mortality of 54 to 69 per cent. in sixty-eight operations, although the operative result was faultless in all but three. He considers gastrectomy a kind of euthanasia, but notwithstanding it must be performed for humane, if for no other reasons. He adds in conclusion, that the prognosis is dubious in every case; it is impossible for the surgeon to know the outcome beforehand, even in the most apparently favorable cases; still surgical intervention should be proposed in all cases that indicate it, and the operation should follow with the least possible delay. Lactic acid is no longer considered a specific symptom of gastric carcinoma, as the palpable neoplasm usually precedes it.—*Cbl. f. Chir.*, January 22.

Death from Inhibition.—Cases are known of sudden death from a very slight blow in certain regions of the body, not severe enough to produce even an ecchymosis. Brown-Séquard explains them by inhibition, arresting by reflex action the heart and the circulation, the exact reverse of the co-ordinated phenomena of reflex motor excitation of which the sneeze is the type. Three phenomena are characteristic of death from

this cause: The absence of agony, the *extreme silence*, no convulsions or foam on the lips; there is no change in the color of the blood, as in asphyxia, and the temperature falls rapidly. But the expert is seldom summoned until these characteristics have passed away, and such cases are apt to be puzzling. The impressionability varies with the age, sex and morbid circumstances. Children are more subject to death from inhibition than adults, and women than men.—*Jour. de Méd. de Paris*, December 19.

Dissecting Aneurysm of the Heart.—A. Vestberg has collected sixty observations of aneurysm of the heart, corresponding to the conception of dissecting aneurysm of the vessels. In most cases it was consecutive to an endocarditis, abscess or rupture of an ordinary aneurysm. In two, to traumatism. The interparietal form is most common. There is no independent wall at first, but a secondary wall forms later, in chronic cases. Rupture occurred in more than half of the cases, but only once outward. In two cases the valves of the aorta were involved; in two others the septal fold of the tricuspid valve, and in four the anterior mitral fold. His communication in the *Nordiskt Med. Ark.* is copiously illustrated.—January 10.

Resection of Renal Tissue for Diagnostic Purposes.—Macroscopic examination of the kidney is not sufficient in many cases to disclose the true nature of an affection, and conservative treatment is much promoted by supplementing the usual means of diagnosing with the resection of a small piece of the parenchyma. Several convincing observations related by O. Bloch confirm the wisdom of the procedure and its absolute innocuousness. He even asserts that the mere opening up of the kidney, freeing adhesions, aspirating fluids, etc., will frequently cure existing troubles, and the resection of a thin slice will confirm the non-malignant character, although to the eye the organ seemed seriously involved and removal urgently indicated. The urine afterward returns to normal with astonishing rapidity. The value to histology of thus obtaining sections of living tissue for study is apparent.—*Nordiskt Med. Ark.*, January 10; eight cases.

The Infestation of Dwellings by Fleas.—The Department of Agriculture, in a recent entomologic circular of information says that it is the *pulex serraticeps*, not the *pulex irritans*, that is more frequently concerned in the infestation of domiciles. As to the removal of the pest the following advice is given: "Every house where a pet dog or cat is kept may become seriously infested with fleas if the proper conditions of moisture and freedom from disturbance exist. Infestation, however, is not likely to occur if the (bare) floors can be frequently and thoroughly swept. When an outbreak of fleas comes, however, the easiest remedy to apply is a free sprinkling of pyrethrum powder in the infested rooms. This failing, benzine may be tried, a thorough spraying of carpets and floors being undertaken with the exercise of due precaution in seeing that no light or fires are in the house at the time of the application, or for some hours afterward. Finally, if the plague is not thus abated, all floor coverings must be removed and the floors washed with hot soap-suds. This is a useful precaution to take in any house which it is proposed to close for the summer, since even a thorough sweeping may leave behind some few flea eggs from which an all-pervading swarm may develop before the house is reopened."

A Vesicant Acarus.—Meguin (*Bulletin de l'Acad. de Méd.*) dwells on the remarkable disease observed in China among the poor, who eat a kind of purslane or arroche (atriplex). The skin on exposed parts becomes edematous and itches severely. The symptom has been attributed to an acarus which is found on this kind of atriplex. But the parasite has not been actually found in any patient. Meguin, however, believes that the theory about the Chinese disease is correct, for in Mauritius

there is an acarus known as *holothyrsus coccinella* (Gervais) which abounds in moss in the cold and damp highlands of the island. Poultry can not be reared in those districts, as the acarus causes fatal pharyngitis. Native children suffer in the same manner. Some specimens of holothyrsus were sent to Meguin. They were all dead. He fixed them by strapping to his forearm. In a few hours they set up severe irritation, edema and prurigo. The live holothyrsus must be a powerful irritant to mucous membranes. It measures under one-fifth of an inch in length.—*British Medical Journal*.

Improved Sutures in Operations for inguinal Hernia.—Prof. S. Duplay and M. Cazin, both of the Faculty of Medicine at Paris dispense with buried sutures in the Bassini and other operations for inguinal hernia by using temporary silver wires. The under row of three U-shaped stitches brings the deep tissues together, beneath the spermatic cord. The ends are twisted tight over a roll of gauze. When coaptation is perfect the cord is replaced and seven wires passed through the superficial tissues, reconstituting the anterior wall of the canal, suturing the pillars and closing the cutaneous wound at the same time with a few additional stitches of the skin if necessary, with very fine wire. The cord has ample space between the two layers of stitches. The superficial threads are removed in seven to eight days. The lower row is not disturbed for twelve to fifteen, and they have been left for eighteen to twenty days without inconvenience. The split ends of the ends are tied together beforehand, to assist in reducing the hernia by the method described in the *JOURNAL* (Vol. 27, page 1348). They consider silver wire much better for these operations than catgut, which is absorbed too rapidly to ensure solidity, and their tests with kangaroo tail tendons, showed that they also were absorbed in fifteen days.—*Semaine Méd.*, December 22.

Medical Representation in Congress.—The editor of the *Texas Medical News* would have a better and fuller medical representation at Washington, and to that end nominates Dr. Stanford E. Chaillé of New Orleans for duty in Congress. He says that his nominee's long experience in matters sanitarian will be timely in the pending and impending discussion regarding quarantine and national organization, for in order to secure the benefits to be derived from a department of public health for the United States Government and State health boards, legislation is indispensable, and the needed legislation can never be secured unless the medical profession is represented in the United States Congress and State legislatures by able members of the profession. These great reforms can never be accomplished in any other way, and to this end we earnestly suggest, as a beginning, to the people of New Orleans and Louisiana, the name of Stanford E. Chaillé as a suitable member for Congress from the district of his residence. In sending Dr. Chaillé to Congress the people of his district would not only confer a benefit upon themselves but, in our judgment, upon the entire people of the United States.

Surgical Intervention in Purulent Peritonitis.—Korte has grouped all the cases of generalised peritonitis from internal causes observed since 1890, excluding all traumatic, gangrenous hernia and other cases in which the peritonitis was secondary to general infection. They number ninety-nine. Seventy-one were operated on, with twenty-five recoveries (32.5 per cent.), and forty-six deaths. Twenty-eight were not operated on: six recovered (21.4 per cent.) and twenty-two died. Although these results are modest, still those who recovered would have undoubtedly succumbed without the intervention, which aims to remove the peritoneal exudate, thus preventing the ulterior absorption of the toxins and freeing the intestines, the abdominal walls and especially the diaphragm, from the extreme pressure. The best results were attained in perforations of the appendix (33 per cent. cured). The earlier the operation

the brighter the prospects of success. If twenty-four hours have elapsed since perforation of the alimentary canal, the chances are reduced to the minimum. The exudate is diagnosed by percussion, palpation in various positions and rectal and vaginal examination. Exploratory punctures are dangerous and should never be attempted unless prepared to follow immediately with the laparotomy. He notes that as the case advances to a fatal termination the general symptoms overshadow the local, and as long as the latter preponderate, no matter how severe, there is still hope.—*Mitth. a. d. Grenzbl. d. Med. u. Chir., ii, 1, 2.*

Sanitation Is the Chief Glory of Modern Times.—Dr. L. Parkes of London has lately given a discourse upon the progress of sanitary operations in the last half century. He gave it as his opinion that it is not too much to say that the chief glory of the closing epoch has been the growth of exact knowledge as to the causes of many of the diseases and adoption of measures, State, municipal and private, that science had indicated as necessary to counteract the diseases and the disease tendencies by which the community was continually assailed. At the present time public health acts and sanitary authorities have revolutionized the lives of the poor. The mortality from small-pox has diminished by 96 per cent. in 1891-95 as compared with the mortality in 1838-42. In the same period the deaths from fever have declined 82 per cent., while since 1871-75 there has been a decrease of 95 per cent. in the mortality from typhus and of 60 per cent from enteric fever. Since 1861-65 the mortality from scarlet fever has fallen 81 per cent., although that from diphtheria has risen in recent years and is now very much the same as it was thirty years ago. In phthisis the mortality has fallen 46 per cent. though it is still high. Cancerous diseases, on the other hand, appear to have increased, nor is the whole of the increase, Dr. Parkes considered, due to more precise diagnosis. Ague, which was extremely prevalent, has been nearly eradicated. Only those who died from acute alcoholism were returned as having died from the effects of drink, yet, notwithstanding the more temperate habits of the people, the deaths from this cause were as numerous as they were thirty years ago. The general effect of improvement in sanitation is that 600,000 persons reach the age of 21 years, who sixty years ago would have died.

Not Held to Standard of Infallibility.—The law does not require of a physician or surgeon absolute accuracy, either in his practice or his judgment. The law does not hold physicians and surgeons to the standard of infallibility, nor does it require of them the utmost degree of care or skill of which the human mind is capable, but that, while in the practice of their vocation, they shall exercise that degree of knowledge and skill ordinarily possessed by members of their profession. This is the declaration made by the supreme court of Nebraska, in the case of *Van Skike vs. Potter*, December, 1897, which was an action brought to recover damages from Drs. Potter and Reynolds for alleged negligent treatment of a knee-cap fractured in a baseball game. The trial resulted in a verdict and judgment in favor of the doctors, which the supreme court affirms. The evidence, the supreme court holds, sustained the finding of the jury that the defendants did not contract with the plaintiff to effect for him a permanent cure, and did not contract to visit and treat him until he was cured. As to whether they had pursued the proper method in setting his knee cap, by wiring the fractured portions together, the supreme court says, "as is usual, the experts for the plaintiff agreed with his contention, and the experts on behalf of the defendants agreed with their contention," and it decides that they were not guilty of negligence in the treatment given the plaintiff, including the leaving the point of a drill in the bone, when broken off in drilling a hole in one of the pieces of the knee-cap, owing to a movement of the plaintiff's leg. Upon

the issue, made by the pleadings, as to whether the defendants agreed to visit and treat the plaintiff until he recovered, the court holds that they were properly permitted to testify that at the date of their last visit to him, they informed him that they should not return unless they should be requested so to do. It also holds that in such a case, text-books on surgery, though standard authority on the subject, could not be read to the jury as independent evidence of the opinions and theories therein expressed or advocated.

Conjugal Diabetes.—Dr. Schram, before the Harvard Medical Society of New York City, is reported in *Medical News*, January 1, as saying that in a series of 5,000 cases Boissumieu found 1.8 per cent. of conjugal diabetes. Most investigators agree that the development of the disease in both husband and wife is not accidental, but that an etiologic relation exists. The facts thus far published do not shed much light on the two theories of causation now held, viz: That the ordinarily accepted causes of diabetes are active in both husband and wife, and that the disease is contagious. Cases have been reported with almost conclusive evidence of contagion, but the nature of the contagium and how it is conveyed are mysteries. In regard to the doubt which has been expressed as to contagion in diabetes, I would like to mention some recently reported cases in which laundresses apparently contracted the disease by washing the clothing of diabetes. However, the question is still an open one. The authorities differ very much, but the French school is inclined to believe that diabetes is contagious. Dr. Schram reports the case of a woman, aged 76 years. She first came under observation seven years ago, and had been married forty-eight years. Sugar was constantly found in the urine in amounts varying from less than 1 to 4 per cent. She refused to submit to rigorous diet in July, 1897, in diabetic coma. Thirst and pruritus had been the most troublesome symptoms. An extensive ischio-rectal abscess developed two weeks before death. One week later the husband's urine was found to contain 3 per cent. of sugar. Symptoms of the disease sufficient to attract his attention antedated his wife's death by about two weeks. Sugar is now found in his urine in abundance, but disappears for a time under diet and opium. He is now 76 years of age and apparently contracted the disease seven years after it was first discovered in the wife, and after nearly fifty-three years of married life. The couple had eleven children, seven of whom are alive and well.

Chief Surgeon Has no Implied Authority to Employ Assistants.—In the absence of expressed authority, there is no implied authority for the chief surgeon to employ assistants. So holds the supreme court of Michigan, in *Burke against the Chicago and West Michigan Railway Company*, Nov. 17, 1897. This was an action brought to recover for medical attendance upon a former employe of the defendant company named Radke, who had received injuries while working on one of its trains. After the employe received his injuries he was first treated by a local assistant surgeon of the company; but on a certain occasion he was taken worse, sent for that assistant, who could not be found, and then the plaintiff was summoned and continued to treat the patient for some weeks. During this time the chief surgeon of the railway company wrote to the plaintiff: "I am informed that you are now attending Herman Radke, an employe of the C. & W. M. Ry. Co., who was injured a few weeks ago. Will you be kind enough to inform me as to his present condition? Has he completely recovered? I would like a history of the case since you took charge of it. Please send your bill for services, itemized, to me if you are through with the case." This letter, the supreme court declares, contains no express authority to attend Radke at the expense of the company. Moreover, it intimates that the company acted prudently in limiting the chief surgeon's authority

in respect to the treatment of injured employes to the employment of regularly appointed local surgeons of the company under contract relations, except in emergencies for temporary services only, because the plaintiff first rendered his bill against Radke at \$2 for reducing fracture and the subsequent items at \$1 each, but charged the railway company at \$50 for the first item and \$3 for each subsequent visit. But on its merits the court holds that a verdict should have been directed for the defendant in this case.

Are Second Attacks of Measles Infectious?—Dr. A. Kebbell writes to the London *Lancet* regarding the question above written, saying: "My attention was first drawn to the subject by a case which occurred in my practice some fourteen years ago. *Case 1.*—A middle-aged farmer with a large family of children had what was diagnosed as a well-marked attack of measles. I quite expected that some others of the family would be attacked, but to my surprise no one else took it, and I concluded that I had made a wrong diagnosis. I am not certain that he had had it before, but from the cases I have seen since I am of the opinion that he had. *Case 2.*—In 1895 a farmer, middle-aged, had a well-marked attack of measles. He had had measles before. He had five children and, his being a small house, no effort was made to isolate the case, but no other member of the family took it. In 1896 there was an epidemic of measles in the village; all his five children were attacked, and he again took it in a severe form. *Case 3.*—A boy, aged 14 years, was ill in the same epidemic with his second attack and a child, aged 6 years, played with him, but did not take it; but six weeks after she contracted it from another child. *Case 4.*—This occurred in my practice in September last. A laborer had a well-marked second attack of measles. He had five children; two of them had not had measles, and although no extra precautions were taken, neither was attacked. I am not aware that this subject has been noticed before, but if my surmise should be correct, it would be very satisfactory to be able to assure patients with second attacks that no isolation would be necessary, and that there would be no risk to any other persons.

Arthritic Basis of Basedow's Disease.—Vigouroux asserts that an arthritic tendency is the general condition, and hepatic insufficiency the immediate cause of Basedow's disease. This assumption explains the arthritic manifestations which so frequently accompany the affection and maintain their independent course. Infective diseases also prepare the soil. Certain symptoms hitherto attributed to the disease, such as alterations in the myocardium and valves should be ascribed to the pre-existing diathesis. This conception that it is a diathetic intoxication with its principal localization in the thyroid gland, on which is superposed the thyroid intoxication, indicates general treatment, hygienic, etc., with special regard to the varying and opposite nutrition shown by the urine, alternating between the arthritic and the opposite characteristics of exaggerated dissimulation. The general treatment is supplemented by faradization of the gland and carotid arteries, including contractility, and reducing both gland and arteries to normal size. With frequent repetition an improvement is obtained equivalent to cure. He considers surgical intervention irrational, dangerous, useless and only allowable as a last resort when all medical means have been tried in vain. Poncet of Lyons, also denounces surgical intervention now, after having advocated it for a while.—*Bull. de l'Acad. de Méd.*, January 11.

Proceedings of the Mobile Convention. The Committee on Publication appointed by the Chairman of the Quarantine Convention of the South Atlantic and Gulf States, submits the following report:

Copies of the resolution offered by the Hon. R. H. Clarke of Alabama, and unanimously adopted by the Convention, together with copies of all other resolutions germane thereto,

were forwarded to each Senator and Representative in Congress, to all members of the Convention and to all persons invited to attend. The cost of printing, stationery, postage, clerk hire, etc., to date, is \$25.55, which subtracted from the amount collected, \$53.75, leaves \$28.20 on hand. From this remainder the expenses of this circular and of further correspondence must be deducted. Manuscripts aggregating 106,000 words have been received for publication, and more are to come. It is estimated that the entire material will make a book of some 350 pages. The lowest estimate for its publication yet received, including binding, wrapping, freight, postage, etc., is, for one edition, \$577.50. If 200 members of the Convention, or others interested in quarantine matters, will subscribe for three copies each at one dollar per copy, the amount will pay for the entire work. The book will be unique and valuable. It will contain a mass of information concerning epidemics, quarantines, camps of detention and refuge, management of refugees; management of railway trains, mails and freights during an epidemic; principles and application of disinfection; theory and forms of pratique and health certificates; proper methods of establishing local, State, and interstate quarantines; and the broad legal principles upon which all these measures must be founded to be lawful and effectual. No such a compilation of facts and authorities upon this subject has ever before been undertaken. All shades of opinion will appear therein as expressed by their ablest exponents. But one edition will be published and the copies will soon be worth far more than their proposed cost. Your Committee makes this report and invites subscriptions to the work. No money is asked for now. As soon as enough subscriptions are received to pay for the cost of the book subscribers will be notified to send in their contributions. If not enough is promised no money will be received, and the manuscripts will be returned to their writers. Your prompt attention to the above is respectfully requested. Write to the Chairman of Committee, Dr. H. A. Moody, Mobile, Ala., stating amount of money you will subscribe and the number of copies you want.

Respectfully submitted,

H. A. Moody, L. E. Brooks, Erwin Craighead, Committee.
MOBILE, ALA., Feb. 24, 1898.

A Peculiar Transaction.—In our issue of Feb. 5 we published an article entitled "Five Years' Successful Experience with a Special Mode of Treating Pulmonary Tuberculosis," by Charles Wilson Ingraham of Binghamton, N. Y. We were not aware that it had any commercial value to the Doctor, but it seems that there was an "African in the woodpile," and we hereby apologize to our readers and other advertisers for having published it. It is only simple justice to say that nothing in the original suggested that it was an advertisement under cover. The following is the reply to a reader who wrote the Doctor in regard to his "special method":

Dr. . . . , Madison, Wis.—*Dear Doctor:*—Your recent communication was duly received and I take pleasure in responding to the same. I thank you for words of appreciation you have expressed concerning the practical aspect of the mode of treating tuberculosis as advocated in my article recently published in the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION. In your letter you requested that I forward you a supply of the compound iodine solution as prepared by myself, and if necessary a hypodermic syringe for the administration of the injections. I would much have preferred to quote you terms and later forward you a definite order, but thinking that the delay would be perhaps disappointing, I have already sent to you the "Introductory Order," which nine out of ten physicians order, and which gives you benefits which do not come with an order made under different conditions. In the 32-page circular which has been mailed you is a list of special hypodermic instruments (p. 28) which are required in order to properly administer the compound. The cost of these instruments almost invariably falls to the attending physician, and commencing with the current year, in response to a large number of requests for better introductory terms, the Bromine-Iodine Chemical Company of this city (Binghamton, N. Y.), general agents for the sale of the compound, decided to send with each introductory order of ten ounces, involving a cost of \$15, the complete hypodermic instrument outfit gratis. I should have stated first that the compound is put up for sale only in one-ounce bottles, and is sold at \$1.50 per ounce. Ten ounces is the average amount required in the treatment of either pulmonary or laryngeal tuberculosis. The average length of treatment is four months, and this creates a cost of less than \$1 per week for the remedy, which is within the reach of all invalids.

The injections are administered once daily. The maximum daily dose is one dram. The injections, as stated in the article in the JOURNAL, are attended with no pain, excepting the puncture of the hypodermic needle, and the most delicate and sensitive invalids can take the treatments.

Since the publication of my first article descriptive of the treatment of tuberculosis with bromine iodine compound, which appeared in the *Amer. Med.-Surg. Bull.*, March 15, 1895, nearly three years ago, the compound has been widely used in every State of the Union, and the results which I have reported have been repeatedly duplicated and better by general practitioners. I have every confidence that you will secure very pleasing results from the treatment, both as concerns percentages of recoveries and permanency of recovery. I shall be very glad to correspond with you further at any future time, and to advise with you by correspondence whenever my advice can be of service. As you have requested, I enclose bill herewith. Fraternal yours,

CHARLES WILSON INGRAHAM, M.D.

Dr., Madison, Wis.,

To Dr. Charles Wilson Ingraham, Binghamton, N. Y., Dr.
Ten ounce bromine iodine compound at \$1.50. \$15.00
Special hypodermic instruments, complete 5.00

\$20.00

Credit special introductory discount on 10 oz. orders . . . 5.00

Balance \$15.00

It is needless to add that the physician to whom this was sent promptly returned the "compound."

Malarial Hemoglobinuria.—Bastianelli, in *Annali di Medicina*, has recently contributed an excellent article upon malarial hemoglobinuria, based not only upon the cases observed in Rome, but upon the careful analysis of the work of others. He asserts that it is practically proved that hemoglobinuria occurs only in infections with the estivo-autumnal parasite. An interesting point is that hemoglobinuria following quinin is extremely rare in Italy, no case having ever been reported from the Campagna. The frequency with which these cases occurs increases, just as in cases of spontaneous hemoglobinuria, as one passes south. Hemoglobinuria due to quinin never occurs excepting in patients who are suffering or who have recently suffered from malarial fever. Spontaneous hemoglobinuria may be at times intermittent, or, as is more common, in single paroxysms. He divides the spontaneous hemoglobinurias into three classes: 1. In the blood there are found estivo-autumnal parasites of the pyrogenic cycle, that is, young hyaline forms. Here the hemoglobinuria occurs regularly in association with the segmentation of a group of parasites, that is, at the time of the ordinary paroxysm. This he terms the paroxysmal hemoglobinuria. 2. In the blood there are found only crescentic or ovoid bodies and pigmented leucocytes, or possibly pigmented leucocytes alone. Sometimes at postmortem the blood is quite negative as regard parasites. They may also be wanting in the internal organs, but from the intravascular melanosis it may be seen that the parasites have disappeared quite recently. In this class the paroxysm of hemoglobinuria is caused by the segmentation of a group of parasites which disappear spontaneously during the attack. The changes left in the blood and internal organs, however, are so great that the paroxysm continues for hours after the organisms have disappeared from the blood. 3. The blood examination is entirely negative, and the only evidence of there having been a malarial infection is the presence of an endothelial, perilobular, perivascular melanosis. The malarial process has come to an end some time previously. Here the attack of spontaneous hemoglobinuria does not depend upon the presence of parasites, but starts without apparent cause. Such paroxysms may be intermittent and repeated at short intervals, but are more commonly single, of long duration and very severe. This form is especially grave and is the "pernicious hemoglobinuria" of Marchiafava, while Bastianelli calls it the post malarial hemoglobinuria. In all probability the parasites which produce the febrile paroxysm play an important causative part in some cases. An ane-

mic condition of the blood, however, seems to be indispensable for the production of the phenomenon, as hemoglobinuria does not occur with the first paroxysm, either in the initial attack or in a relapse. It is rare under any circumstances in the first attack, usually occurring with the first relapse or after repeated relapses. There is also in some cases an individual pre-disposition. Hemoglobinuria does not occur in the most chronic cases of malaria, in those cases where a certain equilibrium is established between the needs of the organism and the function of the hematopoietic organs, but in those cases where the organism is yet freeing itself from the residue of the infection and anemia and melanosis still exist. Bastianelli finally takes up the hemoglobinuria due to quinin. He asserts that: 1. It occurs only in individuals in whom a malarial infection has preceded. 2. The attack is produced constantly every time that quinin is administered, whether it is given while the malarial attack is in progress, or whether it is given while the malarial infection has run its course. 3. Extremely small doses are capable of bringing on an attack. 4. It has been seen in patients who have already suffered from spontaneous hemoglobinuria. It is rare, excepting in the tropics. No doubt there exist cases of hemoglobinuria due distinctly to the administration of quinin.—*Amer. Jour. Med. Science.*

Pittsburg.—It is a matter of some surprise to the general reader to find that Pittsburg is one of the most prominent medical centers, outside the great seaboard towns of the country. This city has a population of over six hundred thousand, and with the towns and villages tributary to it, within a circle of thirty or forty miles, there are nearly a million and a half of people. As a large number of these people are engaged in mining, iron and glass manufacturing, railroading, and water navigation, the surgical work required is immense. In Pittsburg there are fifteen hospitals for the care of acute and emergency cases alone, beside the usual homes for old chronic incurable cases. Only five dispensaries are giving free service to the poor. Of the hospitals the surgical wards are the most prominent. In the West Pennsylvania Hospital, over twelve hundred of two thousand cases were surgical. In the other hospitals the proportion is still larger. The medical cases do not differ from those in other sections, except perhaps in the number of persons of foreign birth, who either display very low vitality or unusual vigor and strength. The air of the vicinity charged with carbon seems not to make any marked difference in the progress of disease. Formerly, Pittsburg was nearly all the time enveloped in a gray cloud of carbon smoke, from the furnaces and mills burning bituminous coal. The use of natural gas changed this, but recently the decline of the gas brings back the old carbon clouds. The postmortems reveal dark discolored lungs in all persons who are residents of the city. It is the opinion of many physicians that this carbon dust is antiseptic, and destructive to many forms of dangerous bacteria. The specialists do not think any marked influence comes from this smoke dust. All of these hospitals have large surgical staffs, and the variety and magnitude of the operations are not exceeded in any city of this country. The Western Pennsylvania Medical College is near the West Pennsylvania Hospital, and the students have rare opportunities to see these cases. This college has a graded three years' course, with a high standard for admission, and averages over three hundred students, with a faculty of professors and assistants, numbering nearly fifty. The building and appointments are modern and the laboratories seem to be well equipped and popular. An outdoor clinic and free dispensary connected with the college, is said to have over ten thousand patients a year. This college is a part of the Western University, and the good judgment of the profession is commendable in most loyally supporting it, rather than organizing rival colleges. The numerous hospitals are many of them sectarian, although the medical staffs are

liberal and generous to each other. Important operations are performed and witnessed by all the hospital staffs, without rivalry or feeling. The West Pennsylvania Hospital is the largest and the South Side Hospital the most modern. The others are good and well managed. The Alleghany County Medical Society is the largest, having a membership of over three hundred. The Academy of Medicine is select and follows the same course as the New York Academy of Medicine or the College of Physicians and Surgeons in Philadelphia, requiring a paper or thesis from all proposed members. The South Side Medical Society is popular and has a large membership.

The mania for medical journals has concentrated in the *Pennsylvania State Medical Journal*, edited by a committee with much ability. This city seems not to be particularly overcrowded. Six hundred physicians of all schools are able to do the medical work. Many of these physicians are well-known members and writers of excellent papers read at the AMERICAN MEDICAL ASSOCIATION meetings. Of these, Drs. Duff, Thomas and others are well known for their surgical studies. Drs. Daley, Lang, Davis and many others are well known as contributors of excellent papers on medicine. Of the specialists, Drs. Ayers, Barham, Diller, McKennan, and others equally noted are prominent. Probably no city in the Union has more practical capable surgeons who are doing all-round surgical work, day after day in a quiet unassuming way, almost unknown to the world abroad. The modern operating-rooms of all the hospitals and the equipments for the best medical and surgical work prove this. In medicine the same thing may be said, the exceedingly practical suggestions and opinions expressed in the discussions of papers at the society meetings, indicate wide reading and intimate acquaintance with the progress of science.

The Academy of Medicine has accumulated a very respectable library and reading-room, which is growing rapidly. The South Side Medical Society has also the beginning of a library and many physicians have large and very valuable collection of books. It is a pleasure to note that while Pittsburg has many local peculiarities, differing from other cities, the profession are loyal to each other, and united on broad principles of science and act together with great harmony. It is also a pleasure to note the absence of low commercial rivalry, which fosters free dispensaries, medical colleges, and advertising journals, dividing the profession into hostile factions. It may also be said by way of criticism, that a body of medical men, whose culture and experience is equal to that of any other city should be more widely known, not only in the literature of medicine, but by a larger representation in the AMERICAN MEDICAL ASSOCIATION.

Illinois Diploma Mills.—The following correspondence by the Secretary of the Illinois State Board of Health is self explanatory:

OFFICE OF THE SECRETARY,
SPRINGFIELD, ILL., Dec. 28, 1897.

Hon. E. C. AKIN, Attorney General, Springfield, Ill.

Dear Sir:—For several months past inquiries have been received almost daily by the Secretary of State and this Board relative to the Independent Medical College of Chicago, and from all information obtainable it appeared that the concern was sending its so-called diplomas over the country to all who applied and tendered the necessary fee. Further inquiry and investigation developed the fact that its methods were almost identical with those of the Illinois Health University, a diploma mill, the charter of which was revoked by the Supreme Court early during the present year, on account of fraud, and furthermore that the "faculty" of both institutions was one and the same person. It seems that after the Circuit Court of Cook County entered a judgment of ouster against the Illinois Health University, the President of that concern, who was also one of the incorporators, with two other "professors" in the corps of teachers, obtained another charter enabling them to carry on a business which the Circuit Court had just determined fraudulent, which decision was afterward affirmed by the Supreme Court. This charter permitted them to grant to students and applicants any degree whatsoever, and it is unnecessary to add that they have

vigorously availed themselves of the privilege. "Degrees" of Doctor of Medicine have been granted to incompetent and unqualified persons ignorant of the rudiments of medicine and the same degrees have made these ignorant and frequently unscrupulous persons lawful practitioners of medicine in several States in the Union, where registering a diploma from a "legally chartered medical college" was the only legal qualification. This obnoxious graduation of quackery into full-fledged doctors of medicine, breathing death and destruction wherever they go, and doing no good to any class of people on earth, except grave-diggers and undertakers, robbing boats of good roustabouts, livery stables of hostlers and barber shops of barbers, to use the words of a former Attorney-General in regard to the Illinois Health University, has brought deep reproach upon the State among others of the Union, and particularly abroad, where the infamous proceedings of this and a few other legally chartered institutions of the same ilk, have lowered the standard of diplomas issued by Illinois medical colleges of good standing, and has caused even those from institutions of the highest grade in the State, which are justly classed among the leading colleges of the country, to be regarded with suspicion.

I deem it unnecessary to add that neither the "professors" or promoters in either the Independent or the parent concern, are legally qualified physicians, or physicians even, to the knowledge of this Board. The President is understood to have a diploma dated 1892 from a college in Indiana which became extinct in 1890, but Polk's Directory, the authority on such matters in the United States, is silent on the subject of his alma mater.

As an illustration of how the "college" grants diplomas to "applicants," I desire to call your attention to one issued to A. H. Neiss, a hostler to a physician in Williamsport, Pennsylvania, which with the entire correspondence and Mr. Neiss' affidavit is enclosed herewith. As you can easily see, Mr. Neiss' entire qualifications were a prescription for tetter and one for piles, and \$25 in cash. Incredible as it may seem Doctor Neiss, for he is a doctor from a legally chartered medical college in Illinois, and according to the privileges granted by this said charter should have the right to practice medicine in Illinois—he can register his diploma and legally and lawfully practice medicine, perform surgical operations of all kinds in the neighboring State of Michigan (in Wisconsin also up to July 1, 1897), and in several States and Territories of the Union, where licenses are issued to graduates of legally chartered medical colleges, notwithstanding that he has no further knowledge of medicine and surgery than that which can be obtained after an attendance of two years in a physician's stable.

I have heard it said that graduates from these so-called medical colleges are legally authorized to commit murder, and while the remark may not have full justification, I very much doubt whether the people of the States and Territories in which persons having no knowledge whatever of the science of medicine, or of the human body in disease, can practice and trifle with the lives and health of the community, by the grace of a charter issued under the authority of the State of Illinois, will feel disposed to dispute the correctness of the statement. In either case, there is every reason to believe that these people, who are now helpless against the invasion of this horde of quacks, will be inclined to regard such charter in the nature of a burlesque, equivalent in effect to one which would empower a lunatic to don a uniform, equip himself with a revolver and club, and act as an officer of the law.

If there be no law in the State providing for the cancellation of the charter of a corporation which is transacting fraudulent business, I would respectfully recommend that you at once take whatever steps are necessary to have the charter of the Independent Medical College revoked by the Courts.

Very respectfully,
(Signed) J. A. EGAN, M.D., Secretary.

Enclosures: Diploma, affidavit, two letters from Independent Medical College, with envelopes, copies of two letters written by Neiss, translation of diploma, circulars, etc., from College (one of these formerly used by the Illinois Health University).

OFFICE OF THE SECRETARY,
SPRINGFIELD, ILL., Dec. 27, 1897.

HON. JAMES A. ROSE, Secretary of State, Springfield, Ill.

Dear Sir:—For years past this State has been disgraced by the presence of diploma mills masquerading under the designation of colleges, universities, academies, etc., which openly and brazenly have conferred almost every degree obtainable in reputable colleges and universities, to all who applied either in person at the institutions, or by letter from wheresoever on the inhabitable globe the applicant might abide, the only requisite qualification being the possession of the necessary

fees. Degrees of Doctor of Medicine have been conferred on ignorant and frequently unscrupulous persons entirely unacquainted with even the rudiments of medicine, many of whom never saw a medical college or heard a medical term, and these same persons, have become legally qualified physicians in several States of the Union, by simply registering their diplomas with the County Clerk, and in others, on obtaining a certificate from the State Board of Health, the issuance of which was mandatory, the applicants being from "legally chartered medical colleges."

This obnoxious graduation of quackery into full fledged Doctors of Medicine, breathing death and destruction wherever they go, and doing no good to any class of people upon earth excepting grave-diggers and undertakers, to use the words of the former Attorney General, to the deep reproach of this State, has been legal, each and every institution concerned and this fraud in law and fact having a charter from the State, and incredible as it may seem, even the degree of Doctor of Medicine granted by many of these corporations (some of which have not even one physician among their incorporators) to persons in Germany, Japan and Australia, who have never left their native soil, are technically as valid as those issued at the college after an attendance and compliance with certain requirements, for many charters permitted degrees of all kinds to be conferred in presence or in absence.

To illustrate the laxity with which charters have been issued, and with what facility individuals convicted of a crime are able to obtain legal authority to go forth and commit the identical crime over again, I will call your attention to the case of Illinois Health University, an institution now happily defunct. During its existence, it was a diploma mill of the most flagrant character and one that caused the utmost disgrace to the State throughout the Union. The Attorney General of the State proceeded against the concern for revocation of its charter. The Circuit Court of Cook County, after considering the evidence, entered the judgment of ouster, and the "university" thereupon appealed to the Supreme Court. Pending the decision of this body, the president of the so-called university, who was one of the incorporators, with two members of the "faculty," procured from the Secretary of State another charter, which in short permitted them to reopen the now practically closed institution, under another name, The Independent Medical College, for almost precisely the same purpose, but however, with greater power, the college now being lawfully entitled to confer any degree, which degrees in medicine, pharmacy, etc., entitled the holders "to all rights and privileges in this and other States to which students and graduates are entitled who receive diplomas from other medical colleges, universities and institutions, in the State of Illinois." Comment on this outrageous privilege is unnecessary.

The Independent Medical College is a worthy successor of its sire. If such were possible it is a ranker diploma mill. "Degrees" are sent broadcast over the world to all who apply.

The Attorney General having cognizance of these unlawful proceedings is about to take steps to have the concern's charter revoked, and order that the promoters of this and the parent institution, may not re-open the concern under a new name and a new charter, conferring even additional powers, I would respectfully ask that you issue no further charters conferring upon any person or persons the right to conduct a medical college, or to grant the degree of Doctor of Medicine, or any miscellaneous degree, without first permitting this Board to give an opinion on the application.

Very respectfully,

J. A. EGAN, M.D., Secretary.

OFFICE OF THE SECRETARY,
SPRINGFIELD, ILL., Dec. 27, 1897.

Hon. JAMES A. ROSE, Secretary of State, Springfield, Ill.

Dear Sir:—I have the honor to request that you will not issue any further charters to persons or corporations for the purpose of treating disease or the prescribing of medicine, until a Court of competent jurisdiction decides that it is lawful for persons not possessing the qualifications required by the Act to Regulate the Practice of Medicine in the State, to prescribe for and treat others.

In this connection I will respectfully invite your attention to a communication from the Attorney General to your office under date of Aug. 24, 1893, in relation to the protest of this Board against the incorporation of certain companies, in which the following remarks occur:

"We are of the opinion that the incorporation of companies for the treatment of diseases, etc., and the prescribing and the dispensing of medicines are of doubtful expediency and should not be encouraged. We advise you, therefore, to withhold the license until you are compelled to issue it by the judgment and order of a competent Court.

"Our reasons for these conclusions are that for the treatment of diseases and practice of surgery, none but persons learned in these professions and licensed under the law are permitted to act. The same applies to the prescribing and dispensing of medicines. This appertains expressly to the profession of the physician, of the surgeon and of the apothecary, which are classified among the learned professions. Under the law we fail to see how a corporation can be licensed to practice one of these professions in the State of Illinois, and to grant a franchise for this purpose we regard equivalent to granting a license."

At present there are several companies in the State legally chartered for the purpose of dispensing and prescribing medicine and treating disease, among the incorporators of which not a legally qualified physician appears. Comment on this state of affairs is unnecessary. Even if the names of licensed physicians appeared in the list of incorporators, there would seem little justification for issuing the charter, as it clothes others not qualified with equal power.

Very respectfully,

(Signed), J. A. EGAN, M.D., Sec'y.

Societies.

The following meetings are noted:

Illinois.—Chicago Medical Society, March 9.

Michigan.—Saginaw County Medical Society, Saginaw, March 11.

Missouri.—City Hospital Medical Society, March 3; St. Louis Medical Society of Missouri, March 5.

New York.—Chemung County Medical Society, Elmira, February 22; New York County Medical Society, New York City, February 28.

Ohio.—Cleveland Medical Society, February 25.

Tennessee.—Dickson County Medical Association, Dickson, March 1.

Texas.—The Lavaca County Medical Society was organized, Hallettsville, March 8.

Virginia.—Richmond Academy of Medicine and Surgery, February 23.

Louisville.

SMALLPOX. Smallpox has been raging in Middlesboro, in the southern portion of the State, and at Jellico. The epidemic has been very mild in character, and almost exclusively confined to the very poorest classes. Dr. J. N. McCormack, Secretary of the State Board of Health, has been on the field in person, assisted by Dr. Arthur McCormack of Bowling Green, and Dr. B. W. Smock of Louisville. General vaccination has been performed under compulsion, a number of cases being found by the officers, in the rounds of house to house vaccinations, which had not been reported at all. Latest advices show that the worst is over, there having been erected detention hospitals and pest-houses which had not been in use before the State Board of Health were notified.

OSTEOPATHS.—Once more Kentucky has come to the front with legislation looking toward the prevention of quackery in the State by passing in both houses of the Legislature a bill which is an amendment to the practice act now in force which will make all applicants to practice osteopathy stand an examination before the State Board. There was a bitter fight in the House against the bill and a whole day was spent in speech making, but the bill was passed by a safe majority and will go to the Governor, who will promptly sign it. The opponents of the bill recognize the fact, that practice in the State will be prohibited graduates of the Still college under this law.

FEBRUARY DEATHS.—There was a total death-rate of 255 against 267 for the corresponding month last year. Consumption caused 33, typhoid fever 12, pneumonia 46, old age 14.

LICENSE.—A bill has just been passed by both boards of the common council taxing physicians a yearly license of \$10. This bill also includes midwives who will have to pay their license fee before being allowed to practice, at the same rate, \$10.

Washington.

HEALTH OF THE DISTRICT.—Report of the Health Officer for the week ended February 26, shows the total number of deaths to have been 105, of which number 66 were white and 39 colored. The principal causes of death were: Diseases of the nervous system, 13; circulatory, 13, respiratory, 24. There were 2

fatal cases of diphtheria, 3 of la grippe, 1 of typhoid fever and 1 of measles. At the close of the week there were 52 cases of scarlet fever in 36 premises and 34 cases of diphtheria in 32 premises, under treatment and isolation.

COLUMBIAN UNIVERSITY HOSPITAL. The "Columbian Women" held a special meeting at the University building on the 28th instant, to meet the faculty of the medical department for the purpose of organizing a plan for raising funds to furnish the new hospital of the University. Plans were advanced and discussed by Drs. A. F. A. King, W. P. Carr, D. K. Shute, President Whitman and Dr. S. H. Green. A special committee for that purpose was appointed, consisting of Mrs. D. C. W. Richardson, Mrs. President Whitman, Mrs. D. Shute and others.

WASHINGTON OBSTETRICAL AND GYNECOLOGICAL SOCIETY.—The 277th meeting of the Society was held on the 4th instant at the residence of Rev. Dr. Cuthbert. The essay of the evening was read by Dr. Bovee, entitled "Permeability of Salpingectomy Stumps." The subject was discussed by Drs. Fry and Stone.

CENTRAL DISPENSARY AND EMERGENCY HOSPITAL.—At the recent meeting of the Attending Staff, the following report was presented for the month of February: New cases, 797; total visits, 2213; prescriptions, 2674; deaths, 3; postmortems, 2; emergency cases, 142; operations, 142; ambulance calls, 33. It was announced that the Senate Committee on appropriations had recommended the usual appropriation of \$15,000 for maintenance, and \$2,000 additional for improvements and repairs.

Cincinnati.

DR. LUDWIG BREMER of St. Louis was the guest of the Academy of Medicine, February 21. The Doctor demonstrated his interesting discoveries of the reaction of the blood of diabetic patients to aniline colors, which discovery by the way only brought the discoverer his well-earned fame years after when it was taken up and substantiated by German authorities. In addition to his experiments with methylene blue, which have been extensively printed, he also showed that Congo red and methyl violet are equally efficacious in proving the presence or absence of the disease: indeed, the essayist stated a personal preference for the Congo red. His experiments are made with dried blood obtained from the finger, smeared on glass slides, which are then heated to 135 degrees C. Macroscopic examination after several minutes staining, shows almost entire absence of color in the diabetic specimen, while with normal blood, control experiments being made simultaneously, a color is produced comparable to that of the eosin stain.

G. A. R.—In view of the great G. A. R. encampment to be held in this city during next September, the medical profession has already organized, under the directorship of Dr. J. C. Culbertson, editor of the *Lancet-Clinic*, for the care of such old soldiers as may be medically or surgically disabled during that week. The organization is of a strict military character, with a director general, medical inspectors, surgeons and assistant surgeons, and numbers in all fully three hundred of the representative physicians of the city. The medical inspectors are composed of those who acted in a medical capacity during the late war; the surgeons from the older, the assistant surgeons from the younger men of the profession. Every man is to be commissioned regularly from the board controlling, and all orders are given in regulation style directly from the medical director. At the various camps reliefs will be constantly stationed, as also at the different depots. Ambulance and emergency corps have been provided. The entire corps will be uniformed while on duty. At various points, drug stores for the most part, near which large crowds are expected to congregate, surgeons will be in waiting, and a yellow flag, the sign of medical attendance the world over, will be conspicuously displayed. Daily sick calls will be paid and records kept of such as require medical attention. A record will be made of this, as well as of all other work done, and it is the intention of the corps to publish as complete a report as possible of their transactions during encampment week. The woman's relief corps have expressed their willingness to cooperate with the medical profession and will be commissioned

as nurses. The apothecaries have also volunteered their services as hospital stewards.

At the regular monthly meeting of the Original Research Society, held February 10, Dr. Horace Whitacre demonstrated, by microscopic sections and photo-micrographs, the identity of clinically diagnosed gliomata of the retina with sarcomata. The slides showed conclusively the endothelial origin and sarcomatous nature of the tumors presented. The essayist stated that the new growths were sent to him with the clinical diagnosis of glioma made by skilled oculists. The discussion which followed brought the general concurrence of the society with the speaker.

THE TRUSTEES of the Cincinnati Hospital held an adjourned meeting the afternoon of February 14, in which it was decided to at once draft a bill and present it to the legislature, asking privilege to issue \$250,000 in bonds, the same to be used in buying land and erecting an isolated hospital for contagious diseases. The matter was brought up before the Cincinnati Academy of Medicine that evening and met with the heartiest endorsement.

By the orders of the city health officer, the consumptive patients at the city infirmary, for the most part cases of fibroid phthisis, are to be removed to the branch consumptive hospital on proving their citizenship to Cincinnati.

THE BOARD OF ADMINISTRATION of Cincinnati has passed an ordinance empowering the health officer to make all the necessary investigations for the purpose of detecting the presence of tuberculosis in dairy cows, with a view to eventually stamping out the disease. With the completion of these investigations, it is the intention of the health officer to introduce a bill in the legislature providing for the removal of all tuberculous cows from dairies.

CHANGE OF ADDRESS.

THE PUBLIC SERVICES.

Army Changes. Official List of Changes in the Stations and duties of officers serving in the Medical Department, U. S. Army, from February 26 to March 4, 1898.]

Major William C. Shannon, Surgeon, will upon the expiration of his present sick leave of absence, report in person to the president of the Army retiring board at San Francisco, Cal., for examination to the board. By direction of the President.

Navy Changes. Changes in the Medical Corps of the U. S. Navy for the week ending March 5, 1898.

Surgeon F. W. F. Wieber, detached from naval hospital, Norfolk, Va. and ordered to the "Albatross" March 10.

Surgeon G. P. Lumsden, detached from special duty at Norfolk, Va., and ordered to the "Franklin."

P. A. Surgeon B. R. Ward, ordered to the "Katabdin" March 1.

P. A. Surgeon I. W. Kite, detached from the "Franklin" and ordered to the naval hospital, Norfolk, Va.

The Journal of the American Medical Association

VOL. XXX.

CHICAGO, ILLINOIS, MARCH 19, 1898.

No. 12.

ADDRESS.

CHAIRMAN'S ADDRESS.

Delivered in the Section on Stomatology, at the Forty-eighth Annual Meeting of the American Medical Association held at Philadelphia, Pa., June 1-4, 1897.

BY R. R. ANDREWS, D.D.S., A.M.
CAMBRIDGE, MASS.

It is the usual duty of the Chairman of Sections of this ASSOCIATION to give, in an annual address, a review of all matters new and important that have a special interest touching the scientific character of the work of the Section to which he may belong. It has been thought best to modify to some extent the nature of the subject on this, the occasion of the Golden Anniversary of the AMERICAN MEDICAL ASSOCIATION, and to give in place a brief history of the work of the Section in the past. The history of our Section is one of which we may well be proud. Our meetings have been full to overflowing with interesting and valuable papers and discussions, and there have been many brilliant lantern exhibits. The work has been in the main along the line of higher themes in the realms of scientific research, and we may rest assured that by comparison with the programs of similar organizations, the work of this Section does not suffer. This statement needs no defense. It is, I believe, already conceded.

In the year 1880 the men who largely represented the brain and sinew of our profession, believing that dental surgery then held a position beneath that to which it was entitled, and believing that such a condition should be remedied, felt it their duty to devote a portion of their time and energies to bring about a change for the better. These men earnestly believed that dentistry was a specialty of the healing art, and as such should have representation in the sessions of the National medical organization. They were actuated by no narrow views. Their sole purpose was the up-building of their profession. Presenting themselves at the meeting of the AMERICAN MEDICAL ASSOCIATION, held at Richmond, Va., in 1881, as delegates from local medical societies, they proposed the organization in the ASSOCIATION of a separate Section on Oral and Dental Surgery. These delegates were Drs. W. W. Allport, T. W. Brophy and Eugene S. Talbot of Chicago; Dr. J. L. Williams of Boston; Dr. G. L. Goodwillie of New York; Dr. Hauxhurst of Grand Rapids, Mich., and Dr. G. L. Parmlee of Hartford, Conn.; all practitioners of dentistry holding medical degrees. Each gentleman constituted himself a committee of one to champion the movement among the members of the ASSOCIATION who were in attendance. They found no opposition whatever; on the contrary the oldest members, and especially the ex-president of the ASSOCIATION, were heartily in sympathy with the movement and anxious to assist in bringing it about. At the morning session

on Thursday, May 5, Dr. Samuel D. Gross of this city, addressing the ASSOCIATION, asked for a suspension of the regular order of business. This motion was granted. He then moved that the by-laws of the ASSOCIATION be so amended as to create another Section, to be known as Section VII, entitled "Dentistry." The motion was favored by Dr. Sayre of New York and Dr. N. S. Davis of Chicago, and was adopted. The object of suspending the rules at this time was for the purpose of creating the Section that it might commence work at that session, the members who were to constitute the Section being prepared with papers for that purpose. Dr. Toner of Washington objected, saying that he was not opposed to the Section organizing and commencing work that year, but he did not wish to make a precedent for future Sections. It was therefore decided that it could not go into operation until the next year, when according to the Constitution and By-laws of the ASSOCIATION, dentistry was officially recognized by the AMERICAN MEDICAL ASSOCIATION.

The Dental Section has met with the ASSOCIATION every year since its formation. The quality of the papers presented, from a scientific standpoint, has been of the highest order. Our place is now here where it seems to me it ought to be, among the specialists of the great guild of physicians, a part of the body of scientific men whose life work is the amelioration of human suffering.

In the annual address delivered before this Section at its last meeting, I gave the result of my investigation of the development and structure of the dental enamel, and in a friendly way criticised some of the views of another writer, who had recently written on the same subject. I have given considerable time to the further investigation of this subject, preparing a paper which I read before the Institute of Stomatology of New York, in February last. This paper was discussed by some of the more eminent biologists of that city, who substantially agreed with me in every point presented to you at our last meeting. The only important point on this subject I have to present as new matter, is the fact, unnoticed before, that some of the globular bodies that have been deposited by the ameloblasts to form the enamel rods, are not homogeneous masses of substance, but are globules having within their substance aggregations of minute spheres (calco-spherites) which for some reason have not coalesced into a mass. These minute globular bodies are held together by what appears to be an envelope or membrane, the whole forming a globule of the same size of what I may call the normal enamel globule at its point of calcification. In some of my sections I have found these enamel globules containing the minute spheres covering quite an area of forming enamel, and they are shown in this condition as they are drawn down into the calcifying rod. They are more than likely calcified in this condition.

It would appear as though it were a fault of structure, perhaps some arrest in the developed mental process. Of this I can not be positive, but the appearance would seem to account for the minute globular structure seen within the rods of the calcified enamel as shown in some of Dr. Williams' illustrations.

A very valuable contribution to the study of the pathology of the enamel, by Dr. J. Leon Williams of London, has recently appeared in the pages of the *Dental Cosmos*. While the subject matter of the text is not altogether new to those familiar with this line of investigation, the lucid way in which the subject is presented, and the very thorough descriptions of the minute pathologic conditions of the tissues involved, together with the great beauty of the large number of illustrations, make it the most notable contribution to the literature of this subject that has yet been presented to the dental profession. He has given a large mass of evidence and the labor must have been enormous. Being familiar with the extreme difficulty of preparing sections of enamel for photo-micrography, and knowing something of the time required, I can fully appreciate the great work Dr. Williams has accomplished. This series of papers follows along the line of investigation given in one I read before this Section in the year 1890, on "A Study in Dental Pathology, Including Pits and Fissures of the Enamel," but is much more complete. I can heartily agree with Dr. Williams in most of the conclusions advanced, and trust we may have this work published by itself in a more permanent form, for reference and for the use of students in our educational institutions.

The year that has passed has pretty conclusively proven that the use of dental cataphoresis may no longer be considered as in its experimental stage, in so far as its investigations relate to the obtunding of extremely sensitive dentine, and its value in bleaching badly discolored teeth. There are a few still doubtful about its future effect upon the life and health of the dental pulp, but the majority of cases reported have been remarkably successful and attest to its undoubted value. The method has also been found to be certain in its action, in fully obtunding exposed pulps prior to their removal. Investigations are being made by this method which promise success in the treatment for the relief and cure of chronic cases of pericementitis by a perfect system of sterilizing root canals at the time of filling. It has been found that almost any good kind of antiseptic can be used; oil of cassia, hydrogen dioxid, chlorid of zinc and silver nitrate have all been tried with success, the method of using being somewhat like that used for obtunding sensitive dentine. This treatment is said to allay the pain in a short time and to place the tooth at once in a condition for immediate root filling. The results obtained by using silver nitrate are significant. Sections made from teeth which had been treated by a solution of silver nitrate by Dr. Bethel of Kent, Ohio, were sent to me for microscopic examination. The higher powers of the microscope revealed the fact that the silver salt had been forced by the current a very considerable distance into the dentinal canals, and each canal had been completely sealed up by it. As the dentine of the root is almost always infected by a putrescent pulp, which sends its organisms into the canals of the root, we can clearly see the importance of this perfect method of sterilization. In the treatment of pyorrhea the cataphoric method of medication has been

found to be a valuable acquisition, and in some cases it has been claimed to have been used with considerable success in facial neuralgia. The very considerable value of the application of the X-ray as an assistance in diagnosis in our specialty, has been repeatedly demonstrated during the year that has passed. It is now possible to make sciagraphs, or shadow pictures, of any part of the mouth and jaws, showing the teeth in proper relation with their alveolar sockets. The roots of the teeth being denser than the bone which surrounds them, show clearly throughout their whole length, and we are thus enabled to note any peculiarity that may exist. In the city of Boston there is one of our profession who has made a special study of this work. He has succeeded in making some very remarkable demonstrations. Many of his pictures are of unerupted teeth deep within the tissues of the jaw. It is possible to show fragments of roots that are the source of obscure troubles. One picture shows a broken pulp canal drill just beyond the apex of the roots that for months had been the cause of a most troublesome abscess. The broken drill was removed, resulting in a perfect cure. It is yet doubtful if we shall be able to determine diseases of the tooth pulp by the X-ray, but authorities assure us that by it it is possible to diagnose necrosis, tuberculosis and exostosis. They claim that diseased conditions cast a shadow differing from normal tissue, and thus the disease is readily demonstrated.

The question regarding the endowment for dental research has recently been brought to our attention by a letter to the *Dental Cosmos* from Dr. C. E. Kells, Jr. He believes that an incalculable amount of good would result to our profession from such compensation for original investigation. The importance of the matter presents itself to us at this time largely on account of the recent magnificent work of Dr. Black and Dr. Williams, and it is earnestly hoped that a fund sufficient to continue these investigations may be appropriated by individuals and societies, that this important work may continue. To quote in part an editorial from the April *Cosmos*: "Nature reveals her hidden secrets to those only who have learned how to question her and who are able to interpret her answers; she demands of her devotees absolute fidelity, uncompromising honesty, unflinching accuracy, absolute self-abnegation and never-flagging enthusiasm in her cause. To meet these conditions requires the expenditure of much time and energy, and just so far as the time of the investigator is occupied with matters foreign to his calling, will his results be curtailed. It would be well to utilize his abilities for the general good by placing him beyond the demands which the necessity for maintenance imposes, thus securing for all those advantages which the entire devotion of his abilities to scientific research would entail."

This matter is a subject that merits our earnest consideration. Within the past year there has been a movement on the part of some of the dentists of the city of Baltimore to bring about the enactment of a law that shall require the examination of the condition of the mouths and teeth of the children of the public schools. The importance of this movement may not at first thought seem to be as serious as it really is, but if we consider it carefully it will be found grave enough to enlist our most careful consideration, fraught as it is with serious consequences, both to the present and future, and a law of this kind

should be enforced in every city in our country. The time of life that the school years cover is very important to the child from the dental standpoint. If the teeth are cared for during this period, the chances favor their permanent retention and for this reason, if for no other, this movement should be urged and encouraged by every intelligent dentist.

The connection between bacterial growths in the oral cavity and severe disturbance of the general health is today well known. There are those who carry more filth in their mouths than they would tolerate on their skin. And this is the condition of the mouths of many of our school children. There are those whose teeth receive very little, if any, care; on inspection they will be found to be covered with a thick deposit in an active state of fermentation. In these mouths we shall find the gums inflamed, suppurating and decayed roots with chronic abscesses continually discharging their putrefactive products into the mouth. The fact that such mouths may be the source of disease and even death has been very much underrated. It is known that pulmonary diseases are brought about by the "inspiration" of germs from the oral cavity. The mouth is a veritable breeding place for the infection of the digestive apparatus.

Prof. W. H. Miller of Berlin by experimentation with cultures, estimates the number of cultivable bacteria in a very unclean mouth at over a billion. Many of these, he thought, were carried to the stomach at every meal, to be replaced by others developing between meals and over night.

I doubt if there is a better culture medium to be found for the growth and multiplication of the pathogenic bacteria than the exposed decaying dentine of the human teeth after the enamel has been destroyed and the dentine decalcified. In it we have a substance perhaps more favorable for the growth and development of these organisms than any other tissue. This in itself is a very significant fact of which we should not lose sight while considering this subject. There should be special care on the part of those who of necessity are brought into close contact with persons suffering from contagious diseases. Many children in our public schools inherit a tendency favoring a development of these troubles. In our crowded, hot and insufficiently ventilated schoolrooms the inhalation of micro-organisms and the cultivation of these organisms in decaying dentine may be, and probably is, the cause of disease and death. Of all the ills that man is heir to the most appalling in its dire results is tuberculosis. Today it is known to be communicated by infection alone, the infecting agent being the bacillus of the disease. It blights all who come within its grasp, sapping the life blood and making the life a wreck followed by misery and death. The children of the poor, especially the immature and sickly, are most susceptible to this disease. In a paper recently published in the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION on tuberculosis infection from food the author, Dr. Charles E. Winslow, tells us that there is an increasing anxiety among thinking medical men due to the resistance of tuberculosis to the advanced curative remedies. All come far short in checking this most formidable of all diseases. The most advanced investigators believe that the colonization of Koch's bacilli in the animal tissue is the cause of the disease. If this be true, and there can be little doubt of it, it gives ground upon which we can work out our own salvation by controlling the spread of the disease.

Our children are fed largely on milk, and the most common disease of the cow from which the milk comes is tuberculosis. Very little milk reaches our city free from a mixture with milk from tuberculous animals. The close relation that exists between the cow and the human family renders it possible for the spread of this frightful malady and for the child's best friend to become his worst enemy.

In an article on carious teeth and tuberculous cervical glands Stark, in the *Revue de la Tuberculose*, July, 1896, notes the frequent association between carious teeth and enlargement of the cervical lymph glands. He examined 113 children with the enlargement of lymph glands and found that 1 per cent. had carious teeth. Not being able to find any other apparent cause for the condition, he concluded that the swollen glands resulted from the defective teeth. They correspond in situation, in time of development and in the degree of enlargement with the condition of the teeth.

The involved glands were situated on the same side as the diseased teeth, the anterior glands being enlarged if the incisors were carious, and those at the angle of the jaw when the molars were involved. Toothache frequently preceded the enlargement of the glands. Stark is of the opinion that the enlarged glands are tuberculous in quite a number of these cases. He reports two in which he was able to demonstrate pretty conclusively that the carious teeth had been the point of entrance of the tubercle bacilli. One, a boy aged 18 years, who had always been healthy and without a family history of tuberculosis, had caries of the molar teeth on both sides with enlargement of the cervical glands. The glands were excised and the teeth extracted. The former proved to be tuberculous and tubercle bacilli were found on cover slip preparations from two of the decayed teeth. The second was a girl of 14 years, with excellent personal history and without a history of tuberculosis in the family. The first inferior molar tooth on the left side was carious and there was an enlarged gland below the ramus of the jaw. The gland was removed and showed definite tuberculous disease. Between the diseased molar and the adjacent tooth and also forming the floor of the cavity in the tooth were characteristic tuberculous nodules with typic giant cells. This latter case is especially interesting as it seems to show that a carious tooth may be the seat of a primary tuberculous focus. With regard to treatment, the glands should at once be removed and the carious teeth be either properly filled or extracted. As a prophylactic, the teeth should be better cared for, and Stark advocates, with Röse, the placing of all school children under supervision.

An interesting case has just been reported to me by a dentist. A boy, about 16 years of age, who was an invalid and whose teeth were so extremely sensitive that he could not or would not have them filled when they were decayed, had trouble with his cervical glands and had them operated on, with relief for a number of years. Afterward it was found that other glands were infected with tuberculous disease and the patient was taken to New York for treatment. The surgeon who performed the operation of excising the infected glands, insisted that all the decayed teeth in his mouth should be at once removed, giving as his reason that the decayed teeth were largely the cause of the infection.

Another case was reported to me, in Cambridge, of

an immature child, who having trouble with the cervical glands, had them operated on by a local surgeon. Some little time afterward symptoms of tuberculosis set in and the surgeon who performed the second operation thought it might be probable that the child had been infected by instruments used in the first operation, the family history showing no signs of tuberculosis. It was stated to me that the molar teeth of this little patient were very largely decayed, and with our present knowledge it seems more than probable that this terrible infection was brought about by the organisms of this disease, which were cultured in the decaying dentine of the molar teeth.

The importance of dealing with this subject must commend itself to us. In many of our States there are commissioners whose duty it is to make examination of cattle suspected of having this disease. The cattle found infected are destroyed. Does it seem less reasonable that we should try to prevent our school children becoming infected? It is a matter that should come home to every family, who would surely desire such supervision after understanding the importance of the subject, if by any possibility it would shield their children from this terrible infection. For this reason they should support a law directing such examinations to be made in our public schools.

The important question we have to consider is: How are these examinations to be brought about? One correspondent states, "if your board of school commissioners is the same as ours, a request of this nature would be looked upon as an unwarrantable piece of interference, a bid to obtain practice." This same writer, however, acknowledges the true charity and philanthropy of the movement. Another says, "if the dental societies are sufficiently in earnest and sufficiently united to pledge themselves to furnish competent members of their bodies at regular periods of each year, a committee from those societies could petition the board of education to appoint an examining dentist to each school." This suggestion, it seems to me, is a most excellent one. Our profession should do more in the way of public charity than it does. We do very little compared to the gratuitous services rendered by the medical profession. The first move should be through the State board of education by the State dental organization. All school children under the care of the family dentist should be required to present to the masters of each school a certificate signed by their dentist. This should be considered sufficient evidence of the healthy condition of the child's mouth. All other children should pass the required examination. An expert could make an examination of each scholar in from three to five minutes. In most of the large cities there are one or more dental colleges with infirmaries for the treatment of all such cases. In these cities the children of the poorer classes should be sent for proper treatment. In cities where there are no colleges, dentists can be appointed by the dental societies to attend to this charity work. The boards of school commissioners in the various States are men of culture and liberal education. They can not fail to see the necessity for such dental supervision, if the matter is presented to them in the proper manner. It will be apparent that such examinations are for the real interest of the children, and an act of real charity and philanthropy, guarding the common welfare and safety of those under their care.

The matter is of such vital importance that we

should seek the co-operation of every dental organization in this country to aid us in our efforts to bring about the examinations and treatment of the mouths of the children in our public schools; who better than they can recognize the justice and importance of this matter. It will save the children from sorrow and suffering, and in many cases such supervision will triumph over disease and death.

LECTURE.

THE MEDICAL PROFESSION.

A Lecture to the Students of Shurtleff College.

BY JOHN B. HAMILTON, M.D., LL.D.

CHICAGO, ILL.

It is with pleasure that I respond to the polite request of the energetic and distinguished President of Shurtleff College and speak to you at this time and place. The subject assigned was part of your annual series, and one naturally congenial to me. I feel, however, very deeply my sense of responsibility of inadequately treating so vast a subject and of doing justice to a profession which is only junior to that of the priesthood itself, and has proceeded from such an early period of time that its records blend with the legends of mythology and the Vedas, Vagas and Charakas of oriental lore. The friends of Shurtleff College should take a deep interest in matters pertaining to the medical profession: for, its name is due to a member of that profession. Dr. Benjamin Shurtleff, of Chelsea, Mass., its founder.

As to the origin of the profession of medicine, modern investigation has shown that the most ancient traditions and records of the nations of the West refer to the "learning and wisdom of the East," and that a study of the origin of the medical art is not finished when the Greek and Latin classics have been explored; but it even goes back beyond the time of the most ancient Egyptian physicians and embalmers. The great school of the Hindu physicians was known to the ancient Greeks, and "when Alexander, after having conquered Persia, was approached, Taxiles endeavored to conciliate the great envoy by presents, saying I shall send to the Great Conqueror, your master, my beautiful daughter, a goblet made of ruby that miraculously replenishes itself with liquid, a philosopher of great knowledge of the sciences, and a physician who has such skill that he can restore the dead." (Malcolm, Hist. Persia.)

The Charaka Samhita, now being republished and translated into English in Calcutta by the learned Pundit Avinash, shows an intimate knowledge of dietary preparations and of the means of preserving health, which is remarkable, considering as we now understand it, that most of their knowledge of anatomy was derived from dissection of the lower animals, as although the rule that there is nothing new under the sun doubtless applies to most things, it does not appear from the records that there were any antivivisectionists in those days. It is known that the ancient Hindus carried their knowledge of astronomy back to the year B. C., 1181 according to Archdeacon Pratt; 1168, B. C., according to Rev. R. Main's calculation, and it is said that the ancient Brahmins, who devoted their entire lives to the cultivation of an education of poetry, astronomy, medicine and religion, excelled in geometry and algebra, which antedated the Greeks, perhaps Euclid himself.

Wise, in his review of the history of medicine among the Asiatics, considers that the Charaka and Susruta were prepared at a very early age, probably from the third to the ninth or tenth century before the Christian era. This conclusion is arrived at from the following considerations:

"1. They were written in the most ancient form of construction of the Sanscrit language.

"2. They were considered to be the production of divine beings, and mentioned by ancient authors.

"3. These medical works must have been written at a time when there was no prejudice of caste, and looking at the sun or stroking a cow was considered sufficient to purify a person who had touched a human bone.

"4. In Charaka the names of the Munis were mentioned, who flourished before mythology was introduced into the Hindu system of religion. They subsequently had in connection with the names all their gods who were afterward most probably introduced by degrees as the various objects and operations of nature were defined and named.

"5. The authors or compilers of these two systematic works on medicine appeared to have flourished in an heroic age, or previous to that in which the Mahabharata, the great epic poem, was written, as they are mentioned in several places of that work, which, according to Wilson, was composed about the second century before the Christian era."

These works are to be regarded as summaries of the knowledge of medicine which was possessed at the time and were probably compiled from medical works previously existing, as the names of various ancient physicians are mentioned. The Hindus made many researches into the chemistry of medicine, and they had a long list of medical plants with the properties thereof, natural salts, and knew of the composition of various alkalies and sulphuric, nitric and muriatic acids. That Hippocrates derived assistance from the Hindus is evident: that he was a great traveler, is mentioned by Galen and Mercurial. In fact, the very names of the medicines used by the Greeks of the Hippocratic era showed their Oriental origin. The practice of the medical art by the Egyptians, at first undoubtedly connected with embalming, is certainly derived from Brahministic lore, and from them in turn it extended to Greece. The Greeks evidently regarded the Egyptians as the first instructors of mankind, notwithstanding they gave themselves due credit for improving and perfecting the knowledge derived from them. Plato says, that "whatever we Greeks receive from the barbarians we improve and perfect." In the Book of Genesis we read that Joseph commanded the *physicians* in his service to embalm the body of his father," which they executed according to the order in the space of forty days.

I referred a few moments ago to the fact that the Ayur-veda, from which the Charaka and Susruta were compiled, were believed to be of divine origin, but we must remember that all ancient countries had faith in the divine origin of the medical art. "The art of medicine," said Cicero, "has been consecrated by the invention of the immortal gods," and we find in the works of Galen a statement that the Greeks attribute the invention of the art to the sons of the gods, who had been instructed by the gods themselves.

The first Egyptian author is said to be Hamon, who was believed to be Hamon the First, of the first Egyptian dynasty. Zoroaster was the next. Pliny, on the

authority of Aristotle, says that Zoroaster lived six thousand years before Plato. After Zoroaster came Thot or Thouth, whom the Greeks placed among the gods and named Hermes, and the Latins Mercurius, and who is the same, according to some authors, as Shem, the son of Noah. Thot, or Taautus as he was sometimes called, was allowed to be one of the counsellors of Saturn, and M. Bouchart has endeavored to prove that Chronos or Saturn was the same as the Jewish Noah. But however uncertain the ancient chroniclers may be on this subject, they agree that Hermes or Mercurius was the author of medicine among the Egyptians, a superstition which has been disproved by the fact that a knowledge of medicine existed, as has been already stated, for many centuries among the Hindus. But I have no desire to confuse you by passing into a discussion of Egyptian and Greek mythology whereby Osiris and Isis were said to have originated medicine, and that Mercury was nothing more than secretary to Osiris and Isis. Indeed, if we undertook to mention seriatim all of the ancient gods and goddesses to whom have been attributed the invention of medicine, the entire time of this lecture would be taken up on account of mythology rather than the profession of medicine. It is somewhat unfortunate that the ancient medical authors, such as Diodorus and others, following the customs of the time, attributed to various gods the introduction of various medicines. It is not astonishing that the poets, with that license which they have been allowed in all ages, should have done so, but the authors of scientific treatises seem also to have been overcome with the spirit of the time. It is probable that Æsculapius, whom the Greeks placed among the gods, was a real personage, although there were several of that name, and confusion might easily result. Cicero said that there were three Æsculapii, of which the first, he said (that one which the Archadeans worshipped) was the son of Apollo. This is the one who invented the probe to probe wounds and apply bandages. The second was the brother of the second Mercury, who was killed by Jupiter. The third was Arsippus, who invented purging and was the first to pull teeth. Neither shall we enter into speculation as to whether Machaon and Podalirus, the two sons of Æsculapius, were respectable physicians and surgeons, and whether Machaon was the older of the two brothers. It is certain, however, that Homer always mentions Podalirus first, nevertheless Machaon, who treated Menelaus, was the more esteemed.

Passing this heroic age we come to the age of Hippocrates, and here it is that the science of medicine became established as a science, and especially the everlasting principles upon which a knowledge of disease is founded, namely, on the observation of actual cases. Although it is not at all probable that the Greek temples were the first hospitals, yet it is to be remembered that in the Æsclepeion Hippocrates on the Island of Cos examined the recorded observations of his predecessors and placed in enduring form his own immortal observations. There was reason why at this time the science of medicine should reach a high state of development in the latter part of the fifth century ante-Christus. This was one of the most remarkable epochs in the intellectual development of the human race. "The contemporaries of Hippocrates were Pericles, a famous statesman; Æschylus, the tragic poet, Sophocles, Euripides, Aristophanes, Pindar, the philosopher Socrates with

his distinguished disciples, Plato and Xenophen, the venerable father of history, Herodotus, and his young rival, Thucydides. In beautiful statuary, there was Phidias, with his illustrious pupils, and many other distinguished names who have conferred immortal honor on the age in which they lived and exalted the dignity of human nature." (Adams.) Both Strabo and Pliny assert that Hippocrates obtained the rudiments of his knowledge from the reports of cases collected in the Æsclepon of Cos.

I shall not at this time and before this audience attempt to give an eulogy of the life and character of Hippocrates, as that has been attested by all succeeding time, but his influence on medicine, it must be confessed, is unsurpassed, and it is admitted today by the best medical philosophers that medical practice at the close of the nineteenth century more closely approaches that of the Hippocratic period than at any previous time. Why, indeed, should not the practice of the art have its standard placed at the same time, as the standard of statuary and eloquence and poetry have been established? As no poet in modern times exceeds Homer, no sculptor of modern times surpasses Phidias; and as no orator of modern times surpasses Demosthenes or Pericles, so no physician of modern times surpasses Hippocrates in his deep knowledge of the philosophy and general principles of the understanding of the medical art. I admit, however, that I myself would rather be treated by one of our hospital internes of the present day than by the prescriptions of Hippocrates; but I speak of the principles which were developed by that great mind who wrote that magnificent series of aphorisms which commence, "Life is short, and the art is long; the occasion fleeting; experience fallacious, and judgment difficult."

The physician of the time of Hippocrates treated his patients on the field of battle, but mostly in hospitals; all chronic diseases were carried to the hospital, and this custom was not abolished until in the time of Augustus, when by a decree, the Greek physicians were made slaves and subject to the caprices and whims of their masters.

We may trace the first education of physicians from the earliest times in a direct line from the Hippocratic temples to the school of Alexandria, and thence to Italy; and under the bright skies of Greece, Asia Minor, Alexandria, and Southern Italy, learning was greatly encouraged and wisdom much increased; but the tyranny of the Romans became fatal to further advancement, and it is seen that absolutely no progress in medical science was made from the time of Galen in the second century down to the medical schools of Salerno in the eleventh, Padua and Bologna in the twelfth, and Montpellier in the thirteenth centuries. The greatest latitude was given to the study of anatomy at the old Alexandrian school under the wise reign of the Ptolemies. Erasistratus, who had dissected animals almost without number for the purpose of establishing his anatomic discoveries, was finally given direction by Ptolemy-Soter to dissect the bodies of living criminals condemned to death, and it is said that over two thousand were dissected under this rule by him and his coadjutors. This was barbarous, but it established certain truths. It was the foundation of the true science of anatomy as at present understood, and the nomenclature given at that time still exists. The science has progressed; the world has generally progressed in wisdom from

that until this time; but there always have been obstructionists, that we are not exempt from the general rule is evident when we see grave and reverend gentlemen straining every effort to prevent the march of science and arrest its development by the stopping of experimentations on guinea pigs or white mice. History will again repeat itself. If the law of our country put its strong hand to stop the physiologic laboratory, to stop experimentation, to stop further progress, what our more ancient brethren in Rome experienced when their scientific studies were stopped and themselves made slaves, mere body servants, will be repeated if the proper members of the profession shall not be allowed to prosecute those needful investigations even at the expense of some of the lower animals and reptilians.

To return, however, to our theme, the profession of medicine was practically suppressed during the long period from the second to the twelfth centuries, a knowledge of the subject being confined to the cloisters, and the priests themselves scarcely daring to exercise it except as a part of religious ceremony in their clerical ministrations. The establishment of the universities in Southern Italy, followed by those of Padua, Bologna and Montpellier, inaugurated a new era, but it may be truly said, however, that it was not until the middle of the fifteenth century that a real revival took place, and even then physicians were not recognized as such for a considerable period. A practitioner of the art was either a specialist devoting himself to cures of hernia, or cutting for stone, or else he was a priest and used the medical art as an adjunct to his office, or a barber-surgeon, and as such obliged *volens volens* to accompany armies in the field. Nor has there been at any time since, a single period when it may be said that the profession of medicine has jumped at a single bound into distinction and a clearly defined position. On the contrary, its growth has been gradual and its recognition likewise gradual. The great discovery by Harvey of the circulation of the blood; the discovery of the use of the microscope; the increase of knowledge of the operations of the organs of the body; the increased knowledge brought about by geographical discoveries and bringing into view certain herbs and chemicals; the discovery of the laws of generation, of animal life; the discovery of the science of bacteriology, or rather its completion, for it too, has come about by degrees, have each, as they have come to the knowledge of the laity, served to place medicine on a firm and enduring basis as a distinct profession.

Quacks have existed from time immemorial; sects have sprung up from time to time, but there have ever remained solid truths, unshaken by the waves of popular clamor, unchanged by the lapse of time, and this has served to maintain a system of medicine practically unbroken from the Hippocratic age down to the present time. Of the quacks that have flourished, there needs little to be said. Some of the most monstrous propositions have been eagerly swallowed by a public ever thirsting for novelty and sensation; and when one has served its turn as a confidence scheme, it is soon succeeded by some other. The same may be said about the sects in medicine which are based on one idea. Each may have some isolated fact as its underlying basis, but having no connection with the broad science itself and therefore generally useless.

I may refer first of all to a new sect denominated

Christian Science, which I believe to be unchristian because it is not humanitarian; nor is it scientific, because it is opposed to the known laws of nature. It has an isolated fact, which is the power of mental influence over disease. It is well known that by hypnotism or mental influence we may exert sometimes a salutary, sometimes a harmful effect on a human mind throughout the body, whereby changes more or less permanent in character may occur. That it may do so in those cases where a delicate balance exists between life and death is extremely doubtful. In the presence of those poisonous agencies which destroy life, such as the venom from reptiles, vegetable poisons such as strychnia, animal bacteria such as from malignant diphtheria, we know that no mental effect whatever can be of sufficient force to arrest the fatal process by which life is destroyed. So then in elevating such a sect to the system of medicine we are committing even a greater folly than our predecessors did when they attempted the apotheosis of Hahnemann and his pellets, or "dilute moonshine," as Oliver Wendell Holmes was wont to call them. I do not appeal here to prejudice, but simply to reason and common sense. It is a fact that the more a substance is diluted the weaker it becomes, the Hahnemannic teachings to the contrary, notwithstanding. If it were otherwise, you had as well shut your eyes to all that occurs in the chemic laboratory; as well admit that an alkali is an acid, or say that no new compound would result on placing a basic metal in contact with an acid.

The newest fad of all, without that connection which enables it to be called a science, is the doctrine called osteopathy. It teaches in brief, according to what I have read concerning it, that all diseases originate in the bones. So far as osteopathy is concerned, the liver is a myth, the gall bladder a toy balloon and the existence of the heart itself a fiction. All known facts in physiology are of no use to the modern practitioner of the art of osteopathy, for by manipulation of the bones and joints he can cure all ills and remedy all diseases to which human flesh is heir. The little morsel of fact contained in this doctrine is that relating to muscular movement, stimulation of the circulation of the skin; in a word, *massage*, a well-known remedy handed down by the ancients from the earliest times. A single remedy, a single method may be adapted for certain affections; may be admirably suited for certain conditions of the body and should be used under appropriate conditions. So, some of the followers of this sect have begun to formulate rules, imbued with the belief that it is the one idea alone which constitutes the sum total of medical science, and its followers have petitioned the legislature of this State to be excluded from the laws governing other practitioners in medicine and surgery, that they may escape that examination which all other practitioners of medicine, including the sectarians, are obliged to submit. I say it in all kindness, I speak it in all sincerity, when I say in this presence and before these young men here assembled, that we should never recognize any sect in medicine as a distinct and separate branch that refuses to accept the established facts governing the generation, the growth, development and life of the human body. Our idea of life itself involves an idea of change. The juices that flow in plants, the blood that courses through our veins, the fluids in the lymph spaces and lymph channels, all these must circulate, all these must change, or else the plant or body

becomes dead and sinks into decay. A knowledge of the forces governing these changes, the laws by which the fluids themselves are formed, the process by which the tissues are regenerated and changed must be known, must be understood, and that knowledge is essential in the understanding of disease. "How can anyone," says Celsus in the second century, "cure a disease when he knows not its cause." "He who understands the cause of disease is best able to cure it." If this statement was true in the time of Celsus, it is true at the close of the nineteenth century and the principle is the same.

Specialism in medicine.—I would not have you understand that anything which I have said in relation to sects in medicine applies in any degree to the practice of well recognized specialists. It is understood that the field of medical science is now so broad, so vast, that no one person can grasp it in its entirety and keep in perfect touch with the advancing knowledge of the time in these several departments; and so in our days the specialist has sprung up again, although it must be remembered, that in the brighter days of the ancients, in the days of the Alexandrian school, specialism had developed to an unprecedented extent, and to a degree which worked its own self-destruction. A man in those days had to have about thirty physicians, one for each class of ailments from which he might suppose himself to be suffering. That was specialism run mad. In our day we may say that there are a few defined and distinct specialties having a legitimate right to exist. It is, however, a fact that the specialists are those who have devoted a period of years (say five or six as the minimum period) to general practice, as without the knowledge which comes from experience the specialist is apt to fall into error. He will examine some particular symptom, but in the range of his specialty he will forget all about the man himself. It is, as a politician once said, that he knew a man whose vision was so acute that he could see a fly upon the barn door but could not see the barn door itself.

Seriously, in order to make a perfect specialist one must be able to make a diagnosis of any of the diseases of the body. Having a knowledge of the whole, he can give each symptom its due weight, and then with the special knowledge which he possesses as to the treatment of the particular organ under observation he will accomplish the most satisfactory results. It is demoralising for a young man to take up a specialty immediately after leaving college. It makes him narrow and untrustworthy. The family practitioner, that is, the general practitioner, has a love and close friendship with his clientèle which, perhaps, while not altogether denied him, are still quite foreign to the specialist. The family consult a special practitioner because they are obliged to, whereas they often go to the family physician as they would go to a friend about matters perhaps which are only semi-professional, and the loss or absence of friendship—I mean close friendship—is a great loss to any man, and especially to a young man just making his start in the world.

Let me refer briefly to the status of the profession at the present day with regard to medical education. It is known to most of you no doubt that a great change has taken place in the last ten years. Ten years ago but a few of the medical colleges in this country required an examination as preliminary to the study of medicine. They trusted entirely to the

doctrine of the survival of the fittest, and expected that a man's success after leaving college depended entirely upon his industry, his energy, natural ability, not less than upon his special knowledge. This state of things no longer exists. All of the best schools in America require a preliminary entrance examination. Some of them extend this requirement to an examination equal to the requirements of admission to the sophomore year of the academic department of a literary school, and others have extended it to the junior year. At the same time there has been a lengthening of the courses of study until now from seven to eight months are required in most of the schools, and some of them have extended the course to nine months. All this extension means additional expense to the medical student; additional expense means the limiting of the numbers in the classes, so that the overgrown classes of a few years ago are not to be expected in the future until we begin to draw students from Europe. Besides that, the profession itself has been overcrowded until the opportunities for remunerative employment have become more and limited; hence the interest of the profession, not less than the scientific interest, required the raising of the standard. Not every man has the mental make-up, the courage, the industry and the peculiar temperament to make a successful physician, even if he is imbued with the high ideals I have set forth. On this point it would be well if our young men took some unprejudiced advice before engaging in a business for which they may find their entire inadaptability when it is too late and thus become professional misfits. Tact, gentleness of manner and amiability of temper with just enough firmness of purpose are characteristics of the successful physician and these seldom come to a man in full measure unless natural to him. They can not be acquired and suddenly put on as one would put on a new suit of clothes. These characteristics must be part of the man himself and a careful study of the character of the many successful physicians shows it. When a young man is found corresponding with this ideal he should be encouraged to study medicine.

But what will become of the physician in the country, away from the larger towns and villages? It is easily seen that his preliminary and regular medical education will cost a vast sum, let us say a thousand dollars a year at a moderate estimate. If now we add to the cost of the collegiate education four thousand dollars, we will see that even at a moderate rate of interest the capital invested will not justify a man in studying for practice in a place where his income will be limited, so that if one enters the profession from this time on, it must be with the distinct understanding that he enters it for his own sake, and not for the sake of pecuniary reward or profit, as the same amount of capital otherwise invested would bring much greater returns. It is natural, then, that we shall expect the physician of the future to be farther removed from the commercial elements which enter into his choice of a profession; that he will be more spirituelle, actuated perhaps by a higher sense of humanity, although it must be said in favor of our profession that, as a rule, they have always been actuated, in the past, by the highest regard for their profession. In fact this sentiment has come to be an abuse, has grown to such a degree that other ranks of society are becoming pauperized. I refer particularly to the so-called dispensary evil.

benefit of the suffering poor, a worthy charity. Today they are being utilized by not only the suffering poor, who are entitled to them, but by the avaricious and greedy and persons whose pecuniary circumstances in no wise render it necessary for them to seek gratuitous advice, and a reaction is now coming on which will certainly lead to the limitation of these abuses, if it does not go further. In one State the aid of the law is sought to be invoked to prevent persons who are not entitled to the benefits of public charity from receiving it. No other profession is called upon for so much gratuitous service to the poor as the medical profession, and as a rule the service is given cheerfully and promptly. I would like the laity to pause for a moment and ask themselves if they know a single profession whose members regularly and persistently from week to week, give their services gratuitously to hospitals and dispensaries, or to institutions of a similar character. As a rule, the doctor in any community is fully abreast, in general information, with the best citizens of that community, and in America he has no reason, at the present time, to complain of his social status. So far as worldly goods are concerned, any practitioner of ordinary ability may be able to live respectably and attain a moderate income. He must never expect to be rich. The rich practitioners as a rule are those who have become so by fortunate marriage relations or lucky investments. Few of them have become rich from incomes derived from their practice. There are many who have acquired a moderate competence, and there are some exceptions to the general rule. This may seem an unpoetic view of the situation, but it is the truth. I had rather picture to you a doctor passing out among the people on his rounds with a shining, smiling face, beloved of everybody, respected of everybody, the admired of a few and the companion of the wealthy, but truth in this manner is inelastic; it is inexorable.

Even a physician in the public service does not receive the same credit as his brother officers in the line. Although the records show that the mortality in the medical department is as great as that in any other branches of the service, and it is known that more men are destroyed by climatic diseases in time of war than are destroyed by the bullets of the enemy, and that the most important means of preserving the strength of the command is to preserve the health of the troops engaged; yet the medical man, not being responsible for any of the military movements, can have attached to himself but a modicum of that military halo which surrounds the officer of the line. This is inherent to his profession, and as it is a true statement it may as well be recognized in making up your minds to enter this branch of the profession.

We have eccentric characters in our profession, and perhaps more than our share of them, but it is scarcely fair to gauge the entire profession by the Sangrados of La Sage, the characters of Molière, or the Abernethys of real life. Our profession is not exempt from a few wolves in sheep's clothing, who are treacherous and tyrannical, unkind to their fellows and assassins of character, but these are exceptional and I believe we have less than our proportion of them as the professions go, but my earnest desire is to see the time when only those study medicine who have natural fitness for its practice.

In this cursory view which I have given of the

away from entering too far certain by-paths which, however pleasant and amusing, are less instructive. I have given you these views as being appropriate truths to spread before any gentleman about to enter the world with the choice of a profession yet before them, and to reiterate the words of old Burton, as true today as when they were written over two hundred years ago, that among the professions "the clergy has the most honor, physicians the most learning and lawyers the most money." I might add, and I think it will be admitted, that of the three professions, that of the physician is the most laborious and the most exacting. If, then, with these facts before you, you choose to become medical pupils and enter the temple devoted to medical science with a view of giving your life to it, let it be understood that you are entering it from pure love of science, for love of humanity, and for the effects upon yourselves of a life of self-abnegation. You may forego visions of wealth and cease to dream of political power or prominence, for these seldom come to the practitioner of medicine. Indeed, in the metropolis of this country at the present day there is a law on the statute books excluding a physician from occupying the position of president of the board of health, the very place one would think a practitioner of medicine would be most useful and perform the greatest service. Let the medical man be content within his appropriate sphere to devote himself to that proper study of mankind, which is man made in the image of his Creator, and you will have the knowledge that although your life may be well spent, characterized all your days by uprightness and virtue, yet the pomp and panoply of circumstance will never be accorded to you, and when you sink to rest, your bier may be surrounded by the weeping faces and falling tears of the poor whom you have aided in your lifetime, but the great bulk of mankind will pass on as if you had never existed. Perhaps this is true of men in general; but if the student be ambitious, it is well that he pause and reflect and face matters as they exist, rather than start out with too roseate visions of what life has in store for him. If he adopt the humble yet noble profession of medicine, he adopts a laborious profession. With all its disadvantages, if they are disadvantages, it may be said that the profession of medicine is eminently respectable; its practitioners rarely suffer from want: they are rarely compelled to beg for bread, and they are treated with reasonable respect by their fellows, for as few of them know how soon they will be called upon to require their services, that anticipatory gratitude born of a lively sense of favors to come is extended to the physician.

But there *are* pleasures connected with the physician's life; at times real happiness when a distinct triumph is made over the arch enemy of mankind—disease; and to increase these triumphs is the constant aim and life study of the physician.

Combined Ileus.—Hochenegg has observed four cases in which the occlusion was caused by several constrictions from adhesions involving the small intestines complicating a cancerous stricture of the transverse colon. As the removal of one did not bring relief, the others were sought and found. In one case there was an ectopic testis; the patient recovered after the fourth operation. In all, the transverse colon was much thickened, while the rest of the walls of the large intestines were normal. In operating the obstruction in the small intestine must first be removed and colostomy established, proceeding later to the ablation of the carcinomatous tumor of the large intestine.—*Wien. Klin. Woch.*, December 23.

ORIGINAL ARTICLES.

THE DIAGNOSIS AND TREATMENT OF URETHRAL STRICTURE.

BY EVERT E. TRACY, M.D.

CHICAGO, ILL.

For convenience of classification, urethral strictures are considered as being of large, medium or small caliber; either plastic-exudative or fibrous in character, and may at any time become spasmodic. Within the folds of the urethral mucous membrane at the point of stricture will generally be found gonococci, and sometimes at this point there will also be found one or more pockets of pus, which, when situated in the deep urethra, may cause chronic prostaticorrhea, or prostatic abscess.

A stricture of large caliber may be defined as any size larger than 29 F. situated either in the deep or pendulous portion of the urethra. This form of stricture will often be overlooked, from the fact that the urethra seems to be of normal caliber, the act of urination being performed without difficulty, and the presence of a stricture only suspected from the slight discharge of glairy mucus observed by the patient; principally in the morning, though sometimes during the day, and often accompanied by pain in the lumbar region, for which he seeks medical aid.

By examination with sounds, in such cases, it will be found that they are passed with but little difficulty until about 28 or 29 F. is reached, when a distinct resistance will be felt, which is caused by contact with the stricture, after the passing of which and upon withdrawal of the sound a few drops of pus or mucus will follow; and upon microscopic examination these will often be found to contain gonococci. The same symptoms which accompany stricture of large are also found in stricture of medium and small caliber, although more pronounced.

Upon examination with the endoscope, which I always make without the use of a local anesthetic (as cocain causes discoloration of the membrane so that the examination is unsatisfactory. I prefer glycerin as a lubricant, as any other substance will obstruct the view so that a perfect picture can not be had). The mucous membrane of the urethra will appear about normal until the point of stricture is reached, when a decided difference in its appearance will be observed. The mucous membrane is now found to be very red or granular at the point of obstruction, showing a plastic exudative secreting pus (plastic-exudative stricture), or thence fibrous bands secreting mucus (organic stricture).

By means of the sound and endoscope any abnormality of the urethra can be detected.

I have always considered Otis' metallic bulbous bougies excellent for locating a stricture, as they can always be rendered sterile.

I never use the ordinary flexible linen boules, as it is impossible to render it aseptic. All other diagnostic instruments are only auxiliary to the sound and endoscope, as with the sound, if properly passed and manipulated, the slightest resistance can be felt and the stricture located as easily in the membranous as in the pendulous portion of the canal, and then by the endoscope the diagnosis can be confirmed, as to the character of the stricture, whether simple plastic-exudative or fibrous organic.

After having made a diagnosis as to the size and

character of a stricture it is easy to decide on a plan of treatment. From a pathologic standpoint, stricture varies. It begins as a thickening of the mucous membrane with a deposit of plastic exudate on the deep connective tissue; later, it develops into a fibrous mass which occupies the submucous tissue and extends into the underlying tissue beyond, thereby becoming the dense fibrous organic stricture.

Some plan of treatment should be devised to cause absorption of this mass.

That form of stricture made up of plastic exudate, either of large, medium or small caliber, I divide into two stages: 1. That which easily yields to the sound and secretes a small amount of pus or blood, when the sound is withdrawn, may be considered the first stage of plastic-exudative stricture. 2. The more organized this plastic material becomes the greater is the sensation of resistance to the sound, and as this material is becoming partially organized, instead of clear pus following the withdrawal of the sound there will be pus mixed with mucus, or clear mucus, in which the gonococci will invariably be found. The same may be called the second stage of plastic-exudative stricture.

In several cases at this stage of the disease, I have found, after introducing a sound and breaking through this formation, that from fifteen to thirty drops of pus followed its withdrawal. When this form of stricture is located in the membranous portion of the urethra the gonococci which lie in the submucous tissue just behind the stricture easily find their way into the prostate, setting up a chronic prostatorrhea or prostatic abscess. In these cases, by introducing the sound into the urethra and making thorough digital examination of the prostate by the rectum, the size and hardness of the prostate can be felt and mapped out, and any fluctuations easily perceived, if pus be present. The prostate lying between the finger and sound can be firmly compressed, and any pus or mucus contained in the ducts of this organ forced out.

Organic stricture of any size, when examined by the sound gives a distinct sensation, to the touch, of dense unyielding resistance. In this form of stricture, after having passed the largest sound which the stricture will admit, it will be found that the next size will meet with a distinct resistance and can not be passed without a great amount of force, which should never be employed.

In the last few years I have adopted a special line of treatment for stricture, especially the plastic exudative. After having located the stricture, and decided as to its character, the urethra is anesthetized with a 20 per cent. solution of cocain containing 5 per cent. of carbolic acid. The object of adding the acid is, 1, to preserve the solution of cocain, and prevent its decomposition by standing, and this is effected so thoroughly that a solution six months old is fully as efficient as a solution freshly made; 2, to further asepticize the proposed point of operation; 3, the acid is a local anesthetic and its addition thus intensifies and prolongs the anesthetic effect; 4, the addition of the acid seems to assist in limiting the local anesthetic action of the cocain, in other words, it diminishes the systemic effect.

The solution is applied directly to the mucous membrane in the following manner: A probe about five inches long and thoroughly roughened is tightly wrapped with cotton for about two inches and is then

saturated with cocain carbolic solution, but care must be taken that no excess is allowed to remain. An endoscope is then introduced to or a little beyond the point to be anesthetized. The cocain carbolic probe is then introduced through the endoscope and held in position, while the endoscope is removed. It is allowed to remain for ten or fifteen minutes, when it is removed by turning to the right as the probe is withdrawn, that is, it is turned in a direction to wind the cotton tighter. If this method be followed and the end of the probe be sufficiently rough, there will be no danger in losing the cotton. In this way anesthesia will be produced which will last a sufficient length of time to allow any ordinary urethral operation.

Under this form of urethral anesthesia a complete examination can be made with the sound, or any other instrument necessary for diagnosis, or a complete internal urethrotomy performed without giving any pain to the patient. In the use of this method, regardless of the strong percentage of cocain introduced into the urethra, I have never had any bad results.

However, knowing the susceptibility of some patients to cocain, it is always well to watch the pulse for any untoward effects. The good results obtained in the use of this method should certainly give it a standing far above the old method of injection, which is not only dangerous but does not always give complete anesthesia.

Allowing that five drops of this solution be used, which would contain one grain of cocain, at least one-half of this amount would remain in the meshes of the cotton. Of the remainder, but one-half could possibly be absorbed in the system, which would be but one-quarter grain.

In the treatment of plastic structure of the first and second stages, I have confined myself to the sound and urethral irrigations with hot water. The patient is supplied with a No. 8 F. soft rubber catheter, in a 5 per cent. solution of carbolic acid, and after instructing him in the aseptic method of using hot irrigations, he is directed to take one irrigation morning and night.

Every two days, sounds should be passed at the physician's office, beginning with two sizes F. smaller than the stricture and carrying them if possible one size above the stricture. When the sound is in the urethra external massage is made over the diseased portion. If after sounding there is a discharge of pus, particularly if it contains gonococci, an injection should be used of 1 to 5 per cent. nitrate of silver.

When stricture is situated deep down in the membranous portion, I not only employ deep irrigations, injections and sounding, but also massage of the prostate by rectum, either with or without the sound in the urethra, in order to force out any mucus or pus liable to collect there.

After this treatment has been carried out for some time a decided improvement will result, and after a few months the patient will be discharged with a normal urethra.

In old organic strictures, however, this line of treatment will not produce such good results, unless carried out for a long time, and even then an internal urethrotomy is often necessary.

Internal urethrotomy simply converts a circular into a linear stricture, and although it gives the urethra a normal caliber, the stricture still remains in

another form, and the normal columnar is changed into pavement epithelium; for this reason this operation should never be performed until other means have failed.

In that form of tight stricture in which we are not able to pass even the smallest sound and the stricture can only be passed by a filiform bougie, I have had good results by the method advocated by Sir Henry Thompson, namely. passing a filiform bougie and allowing it to remain until by its constant presence, pressure atrophy is produced, whereupon a large instrument, a gum elastic bougie, can be introduced. In one case of the kind, by the use of this method I was finally able to introduce a number 16 F., after which by gradual dilatation and hot irrigations I gave the patient a healthy urethra.

In any form of stricture this method of treatment has always given good results. The less organized the exudate the more easy it will yield to treatment, and even in the dense fibrous form of stricture, if the treatment be continued long enough, a healthy urethra can often be obtained without internal urethrotomy.

82 Maple Street.

REPORT OF CASES OF TUBERCULOSIS TREATED WITH ANTIPHTHISIC SERUM T.R. (FISCH).

BY F. E. WAXHAM, M.D.

DENVER, COLO.

The attention of the profession having been quite generally called, of late, to the serum treatment of tuberculosis and some rather glowing reports having been made I desire to add my conclusions, drawn from a limited number of cases. Through the courtesy of the John T. Milliken Co., I was early provided with their antiphthtic serum T.R. (Fisch), which has been described in previous papers published in the JOURNAL. I confess to have entered upon the treatment of tuberculosis with this serum with much confidence. The great value of antitoxin in the treatment of diphtheria inspired the hope that a serum for tuberculosis would prove equally effective. How well this confidence was placed must be judged from the following cases:

Case 1.—C. E. M., aged 40, first consulted me Oct. 26, 1895, and gave the following history: He had la grippe in 1894, after which his cough, which had troubled him somewhat, became much worse. Tuberculosis of upper portion of right lung was discovered in June following, and bacilli at that time were present in the sputum. He was at once sent to Colorado, where he arrived June 29. At the date of his visit to me his cough was dry, harsh and frequent, with very little expectoration; voice husky. Upon examination tubercular infiltration was found in the upper part of the right lung anteriorly, and slight infiltration of left lung posteriorly. There was tubercular thickening and slight ulceration of right side of the larynx involving right vocal band. Under lactic acid treatment and climatic influence the tubercular laryngitis improved and the slight ulceration healed.

Nov. 17, 1897, he again consulted me for examination and treatment. At this date there is tubercular infiltration (fibroid) in right lung as low as third rib; also considerable fibroid degeneration in left lung. Cough dry, harsh and troublesome, with but little expectoration. Bacilli present in sputum, which is very small in quantity; voice husky. Weight 131 pounds, which is 17 pounds less than one year ago.

Treatment and results.—He was placed upon antiphthtic serum T.R. and for five weeks was given daily injections. Commencing with $\frac{1}{2}$ c.c. it was gradually increased to the full dose. About four days after commencing treatment he suffered from a serum eruption upon the back about the points of injection, which caused much annoyance from the itching which it produced. This however lasted but a few days. For some days he seemed brighter and stronger and, as he expressed it, "had

more nerve," but at the end of five weeks daily treatment his appetite had entirely disappeared, he had lost decidedly in weight, was nervous and despondent, could not sleep at night and his cough was much more frequent and troublesome. I had no opportunity of examining his sputum as he left suddenly, hoping that a change of scene and climate might help him. The result of the treatment was highly unsatisfactory. The patient steadily lost ground in every respect.

Case 1.—1, Tubercular infiltration.

Case 1.—2, Tubercular infiltration (fibroid).

Case 2.—Miss C. age 27, consulted me Nov. 20, 1897, giving the following history. She came to Colorado two years ago from Michigan, on account of tuberculosis. At that time she was

Case 2.—1, Tubercular infiltration and softening. coughing badly and had lost ten pounds in weight. She rap-

idly improved after coming here and believed that she had fully recovered. The last few weeks however she has been coughing and expectorating much and losing rapidly in weight. Bacilli are present in the sputum.

Treatment and results.—She was placed upon antiseptic serum T.R., commencing with moderate doses and gradually increasing the amount. For two months the remedy was given daily, during which time the cough and expectoration increased;

Case 3.—1, Old cavity; 2, Tubercular infiltration with harsh respiration. the strength rapidly failed; chills and fever developed and appetite failed. After two months the treatment was abandoned and the following entry is found in the record book. "After two months daily treatment the patient is much worse. She now weighs but 121 pounds having lost 6 pounds during this time. The cough and expectoration is much worse. Appetite is poor. Sweats at night. Pulse rapid and feeble. Has an occasional chill followed by high fever. Bacilli are present in sputum. Physical condition is much worse in every way."

Case 3.—Miss E. O. S. age 27, consulted me Dec. 1, 1897, giving the following history. She has had a cough for eight years and came to Colorado four years ago. She has been failing for the past two months; looks emaciated, and coughs and raises much. The sputum is heavy and bacilli are abundant. At present there is no fever, no chills, no sweats, appetite is fair. She is losing in weight and strength, and suffers much dyspnea upon exercising. Condition of lungs as represented in accompanying cut 3.

Case 4.—1, Cavity.

Treatment and results. Antiphthisic serum T.R. was given regularly and daily for two months together with heart tonics, inhalations of compressed air and greatly increased nourishment. Condition at the end of two months as follows: Dyspnea not as great; sleeps better; appetite somewhat improved and cough not so bad. She still raises much heavy sputum in which the bacilli are as numerous as at the beginning of treat-

has however gained four pounds in weight. Later: At the end of three months' treatment the patient has failed decidedly. The cough and expectoration much worse, much loss of strength and weight.

Case 4.—Age 42, came to Colorado five and a half years ago, with well developed tuberculosis and in very feeble health. Patient improved decidedly under climatic influence and general treatment and remained in fair strength and health until

Case 5.—1, Cavity.

two months since. Of late has been losing ground, coughing more and losing in weight and strength. Examination reveals a large cavity in right lung posteriorly. Jan. 20, 1898, she was given $\frac{1}{2}$ c.c. antiphthisic serum which was repeated daily for four days. A diffuse serum eruption then occurred on the back causing much itching and discomfort, associated with severe pain through the lungs and in the limbs and attended with much prostration, from which the patient did not fully recuperate for several weeks. At the patients request the treatment was abandoned. Result of treatment decidedly bad.

Case 5.—P. D. G., age 40, consulted me December 6. He came to Colorado nine years ago on account of tuberculosis. He so fully recovered as a result of the change and climate that he soon engaged in active business, which he still pursues. The last few months he has been losing strength and weight and the cough has become very troublesome and expectoration has increased. Sputum contains bacilli. Cavity is present in upper right lung. No hemorrhages, no fever or sweats.

Case 6.—1, Cavity.

Treatment. Antiphthisic serum T. R. was given in increasing doses daily, with inhalations of compressed air and increased nourishment. At the end of two and a half months no change is perceptible. Patient has not lost ground but the cough and expectoration still remain and bacilli are still present in the sputum. Antiphthisic serum is still continued in increasing doses. Later: Patient losing ground; has some fever, cough

Case 6.—J. M. C., age 35, came to me for examination and treatment December 28. He gives the history of hemorrhages twelve and eight years ago. He came to Colorado eleven years since; improved rapidly and did well for seven years, when he removed to Pasadena, Cal. Here he remained for three and a half years, but his health again failing he was obliged to return to Colorado. He is now coughing and expectorating freely. Bacilli are present in the sputum, which is heavy and often colored slightly with blood. Cavity in upper left lung. No chills, fever or sweats. Has of late lost seven pounds.

Treatment and result.—Antiphthitic serum T. R. was given daily, increased gradually to full doses, and in addition inhalations of compressed air, careful exercise and full diet. Within two weeks he began to show improvement. Appetite and general vigor improved and at the end of six weeks he had gained seven pounds. Cough is better, expectoration not quite so

and, although not severe, he was confined to the bed and seemed very weak. Upon examination, a very large cavity was found in the upper right lung, with considerable tubercular infiltration all about it. There was much dyspnea upon exertion and the heart's action was rapid and weak. Bacilli present in sputum.

Treatment.—He was given strophanthus, strychnia and antiphthitic serum T. R. The latter was given regularly for two

Case 7.—1, Cavity; 2, Tubercular infiltration.

copious but still heavy and containing bacilli although apparently not quite so numerous as before treatment. Treatment continued. Later: The patient has had a suppurative inflammation of the right middle ear. Cough and expectoration worse again.

Case 7.—I was called December 15 to see M. T., who gave the following history: He came to Colorado ten years ago a very sick man, having had frequent hemorrhages while in the East. He improved rapidly and became practically well, engaging in

Case 8.—1, Area of consolidation.

active and arduous business. Eight months since he began to fail. Business cares, anxiety and overwork began to have their effect. During the summer of 1897 he had quite a free hemorrhage, followed by hectic fever, and was confined to bed for a number of weeks, during which time he lost twenty pounds. By careful treatment, greatly improved environment and rest from business cares he improved and gained fifteen pounds. At the date of consultation he had again had a hemorrhage

Case 8.—1, Tubercular infiltration (fibroid).

months in full and daily doses. The patient gradually improved, gaining five pounds, the dyspnea became much less and the appetite, vigor and strength also improved. At the end of two months, however, another slight hemorrhage occurred and examination of the sputum showed immense numbers of bacilli. Treatment continued.

Case 8.—Mrs. E. W. S. came to me Jan. 12, 1898. Had a slight hemorrhage three years ago. She then came to Colorado, where she improved and remained in good health until four weeks ago, when she was taken with a hemorrhage which confined her to bed for three weeks. Upon examination, find considerable disseminated tubercular infiltration (fibroid) in left lung, and an area of consolidation in lower right lung posteriorly. Cough dry with but little expectoration. No bacilli could be found in the sputum. Present weight 122 pounds; weight in health 142.

Treatment.—Full diet of meat, eggs and milk with daily

Case 9.—1, Tubercular infiltration.

injections of antiphthitic serum T. R. Under this treatment patient decidedly improved in spirit, vigor and strength, and in six weeks increased in weight eight pounds. Treatment continued.

Case 9.—C. P. M., age 34, came for examination and treatment Jan. 27, 1898. He has been coughing for one year, but was very well before that, with the exception of an attack of pleurisy three years ago. He came to Colorado December 7

and at that time had lost thirteen pounds. He is coughing much and expectorating heavy sputum. Bacilli present. Had night sweats before coming to Colorado. Heart's action weak and rapid and there is much dyspnea upon slight exertion. Examination reveals tubercular infiltration in apex of right and lower lobe of left lung anteriorly and lower lobe of right posteriorly. For three weeks the patient did remarkably well as a result of the change to Colorado and under heart

Case 9.-2, Tubercular infiltration.

tonics and increased nourishment. As improvement failed to continue, he was placed upon antiphthisic serum. After one month's treatment no improvement has been noted and no change in the condition of the lungs. Bacilli are even more numerous in the sputum than at the commencement of the treatment. Two weeks later: Has lost three pounds.

Case 10.—Mrs. M. C. came from Canada and arrived in Colorado in November, 1897. Has had chronic bronchitis for a number of years. Respiratory sounds harsh and rasping throughout both lungs. Cavity in apex of right lung. Bacilli are present in sputum. Much dyspnea on exercising.

Treatment.—Strychnia, strophanthus, increased nourishment and antiphthisic serum were given. After three weeks' daily treatment, under the most favorable circumstances, with steady failure, the serum treatment was discontinued with the conviction that it was doing harm rather than good.

Case 10.-1, Cavity.

CONCLUSIONS.

Number of cases treated, 10; cured, 0; improved, 3; worse, 7; bacilli present, 9; bacilli disappeared, 0.

In considering the value of any line of treatment in tuberculosis many factors must be considered. If the patients are pretubercular and the diagnosis is based upon the examination of the blood alone, rapid improvement should be expected from a change of

climate and environment, and too much credit should not be claimed for any specific treatment. When patients with tuberculosis come to Colorado, unless too far advanced, they almost invariably improve and often remain in a fair degree of health for years, if they do not entirely recover. The cases reported would seem fair ones with which to judge the value of treatment. All were long standing cases and, with the exception of two cases which did poorly, all had been in Colorado from two to six years. We may therefore exclude any gain due to climatic influence. Judging from the above cases we may say that antiphthisic serum T.R. does not cure chronic cases of tuberculosis. It does not cause the disappearance of the bacilli. The psychologic effect of daily treatments however even in these cases inspires hope and courage that leads to temporary improvement. It is possible that in incipient cases antiphthisic serum may overcome the disease. If it can be proven to be effective in early cases, thus preventing the necessity of a change of climate, it will indeed be a blessing to mankind. Such proof must come from our eastern confrères, with the careful records of a large number of cases.

RESECTION AND REPRODUCTION OF THE MAXILLÆ.

Presented to the Section on Stomatology at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, June 1-4, 1897.

BY G. LENOX CURTIS, M.D.

NEW YORK, N. Y.

FORMERLY PROFESSOR OF ORAL AND FACIAL SURGERY, NEW YORK DENTAL SCHOOL; AND INSTRUCTOR IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

The purpose of this paper is to show to the profession the importance of special study and instruction in oral and facial diseases, and that these are worthy of the same consideration as is given to any of the fully recognized specialties in medicine. Until they do appear in the curriculum of the medical school, the faculty will not have done its duty toward the student. The field covered by the general surgeon is too great for a careful consideration of any part where such minuteness is required to save and assist nature in doing her work. The surgeon most capable of successful teaching in this line is he who has been a thorough and conservative dentist.

Like produces like; this applies to every department in nature. The periosteum under favorable conditions will reproduce the substance it covered. That of the ramus of the jaw will only make the thin lamina of bone which nature has originally placed there, while that of the malar and the body of the jaw reproduces a dense structure differing materially in texture.

If the function of a part be permanently lost reproduction is not a necessity, nature supplying only that part which is required. If the teeth have been extracted, to remain out, the portion of the jaw which is required to nourish them is not reproduced, but where the teeth are replaced and retained all or sufficient of the bone is reproduced and reattaches them to the jaw. I have seen such in active use for years.

The only condition I can ascribe for the removal of the periosteum is where it is attacked by disease, such as cancer, and the entire structure destroyed. When the bone alone is destroyed, as in necrosis, cystic tumors, or from pressure by resistance of a growth, as tumor of the antrum, I see not the slightest necessity

for removing this natural sheath, but on the contrary every reason for retaining it. I have seen Billroth, Von Burgman, Agnew, Ashhurst, Garretson and other great surgeons resect the jaw, but they invariably employed Huysfelder's, Fergusson's or Langenbeck's method, except in cases of necrosis where but small sections were involved. Liston, Tait, Barton, Mütter and Gross also followed on these lines.

My method to obtain the best results in the preservation of the contour of the jaw is by retaining the necrosed bone in position until the periosteum has been so strengthened by the reproduction as to allow nature's outlines to be maintained, employing it as an interosseous splint. Where it is necessary to remove the bone I retain the contour of the face by gauze packing and change from time to time until the bone is sufficiently reproduced to resume its shape. This requires frequent dressing, so that the amount of pus may be kept at the minimum. The teeth are retained in position by means of interdental splints or ligatures. Where the teeth are lost I place other teeth in the opening when the wound is nearly closed, maintaining them by artificial support and allowing the bone to form around them. Where the destruction of the bone has been great and the periosteum too weak to retain the jaw in position during the process of reproduction I use an interdental splint (as employed by Liston over fifty years ago) in which the upper and lower teeth properly occlude. By hastening slowly the danger of wounding the dental nerve is materially lessened.

In 1886 I operated on a young woman, aged 23, with the following history. Four years previous, after suffering much pain in the face, which was swollen, a fistula appeared in the lower jaw and was diagnosed as being from an abscessed tooth. The gums around the tooth were swollen and inflamed; the molars and second bicuspid were extracted and the pus continued to flow. Her health rapidly diminished, menses ceased and had not returned, although constantly under medical and surgical treatment.

Examination revealed the emaciated condition of the patient. She was suffering from blood poisoning, was highly nervous and hysteric, had no desire for food and had lost the sympathy of her doctors and family. In the left inferior maxilla where the tooth had been extracted, there were granulations. A boggy condition of the mucous membrane extended all along that side of the jaw. Over the ramus it was particularly inflamed. The probe readily passed beneath the periosteum and far up along the ramus. The patient was then too sick for an operation, with a view to best results. The wound was cleansed daily to lessen the amount of pus, and for one month the patient was placed under most rigid restorative treatment with good results. I found that under the local stimulating treatment, bone had been sufficiently reproduced to strengthen the periosteum so that when I removed the dead jaw the contour was preserved. The cause of the trouble I found to be a wisdom tooth lying transversely at the neck of the jaw immediately under the condyle. This, along with the granulations and débris, was removed. The wound was packed continually until healthy granulations filled in the periosteum; the jaw, minus the teeth, was reproduced with all its usefulness. Complete restoration to health and a gain of twenty pounds in weight followed this work. The nerves and vessels in the jaw were not injured and no paralysis resulted.

Before my class at the New York Post-Graduate Medical School and Hospital, on March 25, 1893, I operated on a lad 15 years of age who gave the following history:

Three years before, while at play, he ran against a lamp post, striking the left side of his face and bruising it severely. A year later there appeared on the face, over the malar bone, a hard lump which continued to increase until it was the size of a hen's egg, preventing the boy from seeing, with that eye, objects on the ground near by without bending his head. He had not realized any special pain or discomfort from the tumor. Thinking the trouble arose from the abscessed teeth, his dentist extracted the upper, left, first bicuspid, which showed no evidence of being diseased. I diagnosed an osseous tumor of the antrum, and found that the malar and superior maxillary bones were completely destroyed by the direct pressure against them, only the periosteum remaining. Not only was the tumor directed outward, but downward, depressing the roof of the mouth and extending beyond the alveolar process against the buccinator muscle. An incision was made through the periosteum encircling the teeth, and only a small part of the alveolar process remained intact. This with the teeth was removed, the entire side of the face falling into the cavity made by their absence, so completely was the malar and the superior maxillary bones destroyed. The inferior orbital ridge and zygoma alone resisted the pressure of the tumor. A profuse hemorrhage followed its removal, but was readily checked by hot water. The wound was packed with aristol and gauze, and the contour of the face secured. The periosteum was united by sutures. Through this opening the wound was dressed until the shape of the face was permanently restored. Time of operation was twenty-five minutes.

The following day there was considerable edema which readily subsided. From day to day the dressing was changed until the periosteum could support itself, and in two weeks the case was discharged from the hospital. The antrum was douched daily until restoration was complete. An artificial denture was made to replace those lost, to give the normal fullness to the mouth. In this operation there was no external wound, consequently no necessity for ligature and no scarring of the face, which would necessarily follow had the operation been done on the lines drawn in general surgery. The wound completely healed in six weeks with no deformity of the face. I have seen the case from time to time and it is eminently satisfactory in every way.

On Feb. 3, 1893, I operated on a gentleman 73 years of age who, up to the year prior to that date, was in robust health, never needing a physician in forty years. He stated that he applied to a dentist to have the left superior wisdom tooth, which was loose, removed, it having elongated, owing to the loss of its antagonist. As the dentist was using the forceps, the patient noticed they were covered with blood, but before he could rebel against this outrage, a tooth had been extracted, which was found firmly attached and resistant. He saw that a sound and healthy tooth had been taken out by mistake. The dentist then removed the loose tooth with slight inconvenience. The wound made by the extraction of the teeth did not heal, the gums around it became swollen and inflamed and the remaining teeth on that side were soon loose and sore. In three weeks they were so troublesome that with his

fingers he removed the first molar. He then noticed an opening into the antrum and granulations protruding.

About two months after, the bicuspid was extracted in a similar manner, and in two weeks later the cuspid. The entire side of the jaw became very painful; the patient was unable to sleep or take proper nourishment and had rapidly diminished in strength and health, until at this time. February 3, he was extremely emaciated, not having taken solid food for weeks, and for the past three days only water, because of the great pain in the effort to swallow.

Examination revealed that the entire left half of the jaw and cheek was infiltrated. The microscope showed epithelioma. The characteristic cancerous odor prevailed. An incision was made anterior to the right cuspid and extended back and across the soft palate to the condyle, down the ramus, and forward along the buccal surface of the jaw to cuspid upward and forward until all the mucous membrane to the median line was removed. The entire enclosed area was then resected, leaving only the external portion of the malar bone and the orbital ridge of the superior maxillary in position.

In operating, I removed a portion of the anterior lobe of the parotid gland, along with the duct. The hemorrhage was profuse, but in a moment was completely checked by hot water. The wound was dried, packed with aristol and gauze, no ligatures being employed. Time of operation twenty minutes. The patient made a splendid recovery, slept comfortably much of that night and had but slight rise of temperature. There was some edema of the face, which lasted three days. Patient received most nourishing diet and was sitting up in three days. On the seventh day following the operation, the case was for the first time dressed, no untoward symptoms arising in the meantime. The packing was perfectly dried and scarcely blood-stained; not a drop of pus was present. The wound was repacked loosely, and redressed every third day without a single complication. February 17, the patient was discharged from the hospital with instruction to douche the wound frequently. The wound made rapid progress in healing and on March 13 had almost completely closed, leaving but a single opening into the antrum, so that on March 30, the impression for an artificial denture was taken.

The patient's health had wonderfully improved, he being free from pain and sleeping soundly. He was able to resume the management of his affairs and was again in good health, continuing so until August, 1894, when he contracted pneumonia, from which he died. Two months prior to his death, the cancerous granulations appeared in the old wound. There was no disfigurement of the face from the operation, and the only inconvenience was the loss of his natural teeth, as he was unable to wear the artificial substitute.

A lad 13 years of age was brought to me in March, 1893, giving a history of complete nasal stenosis of some years' standing and a clear history of adenoids. He had been under medical care for years, the physicians failing to recognize the cause of his trouble. I have never operated on a more lifeless and waxy-looking creature. The odor from his breath and body, which was steeped in pus, was most sickening. All of the upper oral and bicuspid teeth were so loose that but for the periosteal attachment, they would have dropped out. There were large sinuses under the lips and the roof of the mouth through which pus

exuded. The periosteum of the roof of the mouth was so filled with pus, that it bagged. All the bone of the superior maxilla anterior to the first molar, including the palatal plate, was necrosed, likewise the palatal bones and the inferior turbinates. The adenoids completely filled the nares and crowded into the antrum of Highmore, breaking down the walls, and advanced until the process of destruction was complete. Pus oozed from all the loose teeth and through the sinuses, nose, mouth, and out through the lachrymal ducts into the eyes. The throat was so plugged up that breathing was very difficult and ptialism extreme. At this operation I removed what I could of the adenoids, opening the nasal passage and partially cleansing the antrums, which was done with great difficulty, as the boy took chloroform badly, owing to extreme anemia; the loss of blood was not so very great. The loose teeth were supported by ligatures until held by the new bone.

The patient made a very good recovery from the operation and in forty-eight hours the improvement was noticeable. The wounds were dressed daily and, through the sinuses, douched every hour. Recovery was so rapid that in four weeks I was again able to operate, this time removing all of the necrosed bone and thoroughly curetting the antrums.

The boy made rapid strides toward recovery and by May 1 I was able to perform the final operation, when I removed the remaining adenoids. Here occurred a profuse hemorrhage, but with peroxid and hot water it was quickly checked. Most stimulating tonics and nourishing diet were prescribed from this on. Recovery was marvelous, and in two weeks the patient was able to walk to my office for treatment. By June 1 he was dismissed cured, having gained forty pounds in weight, having regained his normal color, good appetite and usual strength. He then went to his country home. I saw him again in one year. There was no occasion for treatment; with the exception of a slight imperfection in the alveolar process, where there had been a deep sinus, the gums did not unite and a few adenoids had appeared. The only additional opening, through which I operated, was made where I extracted the left superior molar, this being badly diseased, and through which I was better able to reach the antrum.

To facilitate cleansing of the wound and destruction of the pus, I found electrozone the best of all agents for this purpose.

I have done many cases similar to those stated, and without deformity in any instance. All of them are accompanied by blood poisoning and have usually been treated for rheumatism, malaria and typhoid fever for months and even years, before the error is discovered.

This conservative method is not conducive to a fine collection of pathologic specimens, as a recovery of a part without blemish leaves only the history of the case and the statement of the patient as proof of the malady.

The student should have a chance to see in practice the methods he wishes to adopt. In this city, only recently, at our great university, no end of strife resulted from a determined and successful effort of the dental department to make a place in the hospital for their oral surgeon, with equal right to operate. This was the beginning of the end when all such institutions must of necessity adopt the same course. Why confine this work to so-called major operations,

when they can be simplified to the minor class by annexing such men, skilled in dentistry and medicine alike, to the medical faculty. Let us hope that the controllers of such faculties will appreciate that "knowledge is power" and that new methods are a necessity.

A CASE OF PSEUDO-MEMBRANOUS (DIPH- THEROID) STOMATITIS, CAUSED BY THE STREPTOCOCCUS PYOGENES.

Presented to the Section on Laryngology and Otology, at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY LOUIS JURIST, M.D.

PHILADELPHIA, PA.

Although diphtheria and diphtheroid diseases are of very frequent occurrence, the mouth and tongue are but rarely affected, in spite of their exposed position and liability to injury. The micro-organisms which are responsible for the deadly group of pseudo-membranous inflammations must traverse the mouth in order to gain access to those structures in which they most commonly develop their nefarious activity, yet the oral mucous membrane, where the conditions in general are very similar to those at the points of selection, is practically immune to the influence of the micro-organisms in question.

It is the great rarity of oral diphtheria that has led a number of authors to deny its existence as a primary disease, while admitting its possible, but very infrequent occurrence as a secondary manifestation.

While the case I report is, etiologically, not one of true diphtheria, since it was not caused by the Klebs-Loeffler bacillus, the invariable producer of the disease, it yet presents the clinical features of diphtheria, and but for the bacteriologic examination, would have passed as an unusual example of that dreaded malady, just as many instances of pseudo-membranous throat affections are termed diphtheritic, when in reality they are not due to the bacillus of diphtheria.

The history of my case is as follows: Late at night, July 22, 1893, I was called to Maggie M., age 20. The alarm of the family and the statement of my summoner that she was choking to death, seemed well founded. Sitting in a chair, the tongue enormously swollen and protruding as a thick mass from the mouth, the facial expression one of anxiety and suffering, the young woman presented a most distressing aspect. It was learned that some days previously the patient had had an attack of vomiting and diarrhea, which had yielded to treatment. Shortly thereafter the tongue began to swell and the present condition supervened.

The floor of the mouth and the under surface of the tongue were covered by a thick grayish membrane. The tongue was swollen and rigid; its dorsal aspect somewhat coated, but free from false membrane. There was a repulsive odor of the breath. An examination of the pharynx was rendered impossible by the intumescence of the tongue. The skin was moist and cool, pulse rapid and feeble, temperature 101 degrees.

During the next two weeks the general condition remained about the same; the membrane gradually spread to the upper and lower lip, confining itself to their inner surface, and also crept along the cheek, being particularly limited to that portion in contact

with the upper and lower teeth. Frequent slight hemorrhages occurred, becoming freer if portions of the membrane were forcibly detached. During the height of the disease the submaxillary lymphatic glands were enlarged, while a well marked edema involved the entire face and neck, extending from ear to ear. Deglutition, the diet naturally being restricted to fluids, was accomplished fairly well, when the head was thrown back and the liquid poured into the oropharynx.

As the patient slowly improved, an examination of the pharynx became possible. Two oval, distinctly outlined patches were noticed on the hard palate, close to the last molars of each side, and extending toward the median line, but without coming in contact. There was no membrane on the soft palate, the uvula, the tonsils, or the palatal arches.

After a time the membrane ceased to form, the tongue diminished in size and eventually regained its normal proportions and contour.

The internal treatment was supporting. Locally, the use of hydrogen dioxid, followed by corrosive sublimate, was instituted. Steam inhalations of sodium benzoate were employed. As improvement did not follow, the inhalations were, after a few days, superseded by applications of electrozone. After thorough cleansing of the parts, pledgets of absorbent cotton saturated with this liquid were placed against the affected areas and frequently changed.

Upon my return to the city after an absence of several days, I received the following letter from Dr. Kinnier, who had charge of the case:

I thought perhaps it might be of interest to you to know what has been the line of treatment in the case of Maggie M., since you last saw her.

I believe the electrozone did good, but unfortunately there was not enough to give it a thorough trial. After its discontinuance the mouth became much worse, the peroxid, full strength, making very little impression.

As the case seemed extremely urgent, I resorted to argenti nitras (grams 1.3 to c.c. 30) applied three times a week, and potassium chlorate, gram 0.32, every two hours, night and day. The result was magical.

There was quite copious bleeding on two occasions, due to the ulceration on the left side of the tongue extending into a small vessel. The bleeding was of decided benefit, as the inflammation immediately subsided. There remains now only a small patch about the size of a three cent piece on the buccal surface of the right side, near the angle of the jaw.

One year later there was a distinct scar which prevented protusion of the tongue.

Regarding the course of infection it was impossible to obtain any precise data. All that could be learned was that the patient had come in daily contact, in her workshop, with a young woman in whose family there had been two recent deaths from diphtheria. The patient's teeth were wretchedly kept and the majority carious.

In order if possible to determine the ultimate nature of the case, a piece of membrane was sent to Dr. Eshner, who submitted it to Dr. A. C. Abbott of the Department of Hygiene, University of Pennsylvania, for bacteriologic study. The following is Dr. Abbott's report:

Dr. Almstead, our assistant, has gone over carefully, under my supervision, the piece of membrane from Dr. Jurist's case of supposed diphtheria of the tongue, and we fail to find anything either in the way of bacteria or tissue changes, to justify the opinion that it is of a diphtheritic nature.

The only bacteria that are present in conspicuous numbers are streptococci, and I feel reasonably sure that they played the etiologic role in the production of the trouble. There are often exudative inflammations on and about the pharynx of this origin that can not be differentiated from diphtheria

except by bacteriologic methods, and this is very probably one of them.

In view of the foregoing report the case can not be considered one of diphtheria of the mouth, but must be classed among the so-called diphtheroid affections. In examining the literature on the subject of diphtheritic inflammations of the mouth (using here the adjective in its widest or anatomic sense, that in which Virchow employed it), we find the earliest reference in the work of Aretæus.¹ The remarkable passage in the *Syrian Ulcers* in which Aretæus portrays the essential features of diphtheria in a wonderfully complete manner, contains this reference to the mouth: "When this (the ulceration of the tonsils) eats outward toward the mouth, it reaches the uvula and destroys it. Likewise it may involve the tongue, the gums and the alveoli, until the teeth become loose and turn black. The phlegmon may also extend to the throat. Such patients die in a few days from the inflammation, the fever, the fetid odor and the hunger. If, however, the disease passes through the windpipe into the thorax, it then kills on the same day, for the lungs and the heart can not endure such an odor, nor the ulcers, nor the ichor, but cough and dyspnea are developed." Van Swieten,² the commentator of Boerhaave, observed the occurrence of diphtheria of the mouth during an epidemic at Leyden, in 1738.

In the present century we find that Bretonneau³ was the first to give a clear description of the disease, but he, as well as the earlier writers did not distinguish the ordinary ulcerative stomatitis, so common on the gums at the roots of the teeth, from the rarer diphtheritic form. That Bretonneau, however, did see cases of the latter is evident from one of his papers, in which he says that toward the end of the epidemic at Tours he observed eight children in the same ward seized with "*gangrene scorbutique*" of the gums of the right side. On the second day three had membranes on the corresponding tonsil, with enlargement of the submaxillary glands. In all, the borders of the tongue and the internal parts of the cheek were covered with membrane. In some cases, he adds, the disease may extend into the pharynx and larynx, a calamity which he believes to have been averted in the eight cases by the vigorous local use of hydrochloric acid.

Trousseau⁴ shares the views of Bretonneau, but seems to consider extension from the mouth to the pharynx and even to the larynx as quite common. Among contemporary writers we note that Butlin⁵ doubts the existence of primary diphtheria of the tongue, admitting, however, as a rare possibility the occurrence of diphtheritic inflammations upon accidental or operative wounds of the tongue. The liability of the tongue to secondary diphtheria is also small. According to Jacobi,⁶ the disease may be primary.

Forchheimer,⁷ in his excellent series of papers on stomatitis in the *Archives of Pediatrics*, treats of a croupous and diphtheritic form. The first is never primary, but "is always a complication of angina crouposa. The second occurs rather frequently in birds and calves, and has occasionally been observed in man." The distinction which Dr. Forchheimer makes brings up the much discussed question of the identity of croupous and diphtheritic inflammations. I have no desire to dwell upon this subject except so far as to say that there seems no longer to be any

justification for the separation of those conditions into two autochthonous diseases.

J. Lewis Smith⁸ states that the diphtheritic pellicle sometimes forms in the cavity of the mouth, generally in small patches except upon the tongue, where the pellicle extends more deeply.

An interesting case, one of true primary diphtheria, is reported by Thiercelin.⁹ The patient, a woman aged 30 years, complained of pain in opening the mouth, had anorexia and a little fever. On examination the lower surface of the tongue and the floor of the mouth were covered with a whitish-gray membrane. The tongue was not swollen, its dorsal surface bore a thick coat but no membrane. The internal aspect of the cheeks and the external surface of the gums, especially the lower, presented false membranes. There were also two patches on the lower lip, vestibular surface; none on the upper. At the base of the teeth there was some ulceration, but apparently not of a diphtheritic nature. The disease did not extend beyond the pillars of the fauces; the pharynx was perfectly free. The submaxillary lymphatic glands were swollen, mastication was impossible; an intense fetor and salivation were present. An examination of the membrane revealed the presence of an abundance of Klebs-Löffler bacilli, which were also demonstrable in serum cultures at the end of twenty-four hours. There were no streptococci, no staphylococci. The patient recovered.

Sevestre and Gaston¹⁰ conjointly report a series of cases of membranous stomatitis, the features of which, according to the authors, entitle it to be considered a new clinical entity, and they give it the name of *stomatitis impetiginosa*. It attacks debilitated children, especially those recovering from measles or whooping cough. A whitish, adherent membrane, very similar to the true diphtheritic exudation, forms in the mouth, on the gums, the internal surface of the cheeks and lips. On the tongue the formation of pseudo-membrane is rare and occurs in small, elongated patches, particularly on the borders and tip. In their series of ten cases the involvement of the tongue was noted but once, in a child of 21 months. The lymphatic glands are only slightly tumefied. In nearly all instances the disease is associated with impetigo of the face. Bacteriologic study demonstrated the presence in every case of the staphylococcus pyogenes aureus.

At the suggestion of Rendu, Sevestre¹¹ tested the reaction of the saliva in a case and found it acid. A very curious disease, also characterized in part by the formation of a false membrane, is described by Siegel,¹² who observed it in epidemic form in the neighborhood of Berlin during a period of three years, from 1888 to 1891. The membrane is found upon the swollen and edematous tongue in the form of a yellowish, often deep black or even inky, firmly adherent layer. The gums are swollen and the teeth are loosened. Eruptions petechial or vesicular are frequently present on the legs and arms; constitutional symptoms are grave. Not rarely the disease is fatal. Siegel, who terms it *stomatitis epidemica*, regards the affection as identical with the foot and mouth disease of cattle. Owing to its rarity the proper nosologic position of *stomatitis epidemica* remains still somewhat obscure. It probably bears no relation to diphtheria.

Wharton's¹³ case, a boy aged 6, had the tongue much enlarged, partly protruding from the mouth, covered with a thickened epithelium which could be stripped

off without much difficulty; there was a patch of white membrane upon the inner surface of the right lip and inner surface of the right cheek, the neck was swollen, submaxillary lymphatic glands much enlarged. Bacteriologic examination revealed the Klebs-Löffler bacillus, the guinea pig succumbing to subcutaneous inoculation in seventy-three hours.

The chief points in the present paper may be summarized as follows:

1. True diphtheria, *i. e.*, a disease caused by the Klebs-Löffler bacillus, may occur in the mouth both as a primary and as a secondary manifestation.
2. Pseudo-membranous inflammations, clinically indistinguishable from diphtheria of the mouth, may be produced by other micro-organisms.
3. As far as the cases reported go, we must accord this ability to the streptococcus pyogenes and to the staphylococcus pyogenes aureus.
4. Grave septic states have not been observed in those cases where the disease remained limited to the mouth.

ACUTE MYRINGITIS.

Presented in the Section on Laryngology and Otology, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, June 1-4, 1897.

BY RALPH W. SEISS, M.D.

PROFESSOR OF OTOTOLOGY IN THE PHILADELPHIA POLYCLINIC, PHILADELPHIA.

The subject of acute myringitis is usually disposed of in a page or two in most text-books, and one of the most popular modern treatises does not even mention it, yet its widely dissimilar course in different patients, its tendency to produce serious lesions, and its painful character render the disease worthy of most careful study. Acute myringitis differs much in type, each having its own pathology, symptomatology and treatment; it is therefore convenient to divide it into simple, desquamative, hemorrhagic and suppurative varieties.

Simple inflammation of the drum membrane is caused by disease of the external auditory canal, of the Eustachian tube and middle ear, or by direct injury from foreign bodies, irritating fluids, cold water, etc. It is one of the commonest of aural maladies, the ordinary cases of slight earache being usually examples of this disease. The symptoms are usually pain, slight deafness and throbbing tinnitus. Pathologically the condition is one of active hyperemia, with serous infiltration of the layer of the cutis. On inspection the drum shows intense congestion of its upper and central portions, and the malleus may be more or less obscured by swelling. This condition usually promptly subsides under appropriate treatment, or in some cases even spontaneously, or it may progress into the desquamative form.

The symptoms in the latter case are always much

more marked than in the earlier stage, pain is often great and boring in character, and deafness may be nearly complete from combined swelling and mechanical obstruction by the large epithelial masses. The epidermis macerates, becomes loose and is finally shed off in large flakes, occasionally representing the whole outer surface of the drum, and the raw corium is thus exposed; the swelling is marked from both serous and cellular infiltration, and the whole membrane becomes friable and soft. Examination may be impossible until the external canal is cleared of the shed epithelia; when the drum is brought into view the position of the manubrium is recognized only by the red lines of engorged blood vessels, and the whole fundus may have a raw beef-like appearance.

The prognosis is recovery in a few days under properly applied therapeutics, but perforations and permanent thickening are exceedingly apt to occur if the case is neglected, or the acute condition with pain and deafness may continue even for weeks. The amount of desquamated skin thrown off is often surprising, the fundus sometimes being found completely blocked with it every two or three days for a considerable period. This is one of the ways that the large dermoid masses, occasionally found in the external auditory canal, are formed.

Hemorrhagic myringitis Politzer considers a rare disease and the writer has not seen above 20 examples in his last 2000 ear cases. It seems to occur only in ears which have been previously damaged by chronic disease—sclerosis, cicatrices, dense impacted cerumen plugs, etc. The blood vessels appear to give way at one or many weak points, and myringial apoplexies result. The symptoms do not differ from those of the desquamative form, but there appears to be more tendency to constitutional involvement—fever, malaise and weakness—and deafness is more apt to be extreme.

The diagnosis is easy on inspection, the dark purple blebs, varying in size from a No. 8 to a No. 1 shot, standing freely out from the generally congested surface of the drum, or from the canal adjoining. Hemorrhagic myringitis is especially apt to run a somewhat chronic course, successive crops of blebs appearing; even under treatment the duration is apt to extend to at least a fortnight. In one case treated by the writer about eighteen consecutive blood blisters formed and were cut, and the treatment had to be continued for about a month. This case occurred as a sequel of epidemic influenza and chronic aural catarrh, and was characterized by constitutional depression quite out of proportion to the severity of the general disease; the drum finally cleared up completely without any permanent injury to hearing.

Suppurative inflammation of the membrana tympani may occur from septic disease of the middle ear or the external auditory canal, or in rare cases is purely primary, such instances not being very uncommon from sea-bathing. In the primary cases a true abscess occurs between the layers of the drum, which may break outwardly, with or without complete perforation of the membrane. Inspection may show the bulging abscess in addition to intense engorgement, or an ulcer the result of its rupture or perforation may have occurred. The symptoms are generally quite severe, the pain being more like that of general suppurative otitis in character. The prognosis is often more favorable than in either the desquamative or hemorrhagic types, a single treatment often effecting a cure.

The therapeutic management of acute myringitis is most important, as the tendency of the disease to produce permanent lesions can nearly always be obviated by proper care and the pain and discomfort promptly reduced to a minimum. In the simple acute type syringe irrigation with a warm boric or carbolic acid solution has a most happy effect; at least a pint of fluid should be used, great care being taken to cause no pain or traumatic injury. The surplus fluid should be lightly mopped from the canal with a soft cotton tuft, and the meatus loosely plugged with gauze or cotton. If the engorgement is intense and desquamation or suppuration is feared, it is my habit to lightly dust the drum with the calendulated boric acid formula of Sexton; this often appears to give great comfort and seems free from objections.

If the Eustachian tube and the middle ear are involved their treatment is most important. This should consist of sedative sprays applied to the nasopharynx, preceded, if much swelling exists, by the very cautious use of a weak cocain solution.

When engorgement is largely limited to the tube and post-nasal region—an acute Eustachian salpingitis of which the myringitis is a sequel—the cocain solution and also the subsequent wash is best applied by the syringe catheter, the utmost gentleness being used. Inflation of the middle ear by Politzer's or other method has never had any but an unfortunate effect, in my experience, when used in this disease; many cases that would have recovered without any treatment are by it converted into examples of acute middle-otitis, and it is only mentioned here in order to condemn it absolutely in true myringitis.

Desquamative inflammation of the drum is a much more serious affection than the preceding, as actual destruction of tissue has necessarily occurred, and calls for very careful management. It is of the utmost importance to entirely clear the aural fundus of the decomposing irritating masses, as their presence is a fruitful source of further mischief. Syringing should be employed as above suggested, but owing to the insolubility of the epithelial masses, their removal can seldom be perfectly accomplished by this means alone. Burnett's double-pointed screw or the writer's L-shaped hook are the most satisfactory instruments for its removal in trained hands; Sexton's or some similar forceps may be employed by the somewhat less dextrous. After thorough antiseptic irrigation and cleansing, the fundus should be thoroughly dried and very lightly dusted with dermatol or the calendulated boric acid. The nose, throat and Eustachian tubes should also receive appropriate treatment if at fault; even the cases due to local traumatism are benefited by relieving a coexistent nasal or pharyngeal congestion; the naso-laryngeal tract should therefore always be subjected to close scrutiny. Rest within doors and tonic treatment are often indicated in desquamative myringitis, and if the symptoms do not at once subside the patient should receive local treatment daily. Persistent thickening may subsequently call for massage, Eustachian catheterization or judicious applications of iodine ointments to the drum after all the acute symptoms have subsided.

The hemorrhagic form of myringal inflammation has been best treated, in my experience, by freely incising the blebs as they appear, gently syringing out the blood clots and insufflating a boric powder containing from 5 to 10 per cent. of alum, a light

coating only being applied to the fundus. The nasotubal tract always needs attention, and tonic treatment is generally urgently needed, these cases occurring only in persons of poor vitality with weak vasomotor nerves and vulnerable vascular systems. As the disease has a strong tendency to recur, any existent chronic affection of the ear should be removed as thoroughly as possible and the general system brought up to its highest tone. The writer has seen several cases in which glaucoma occurred in patients who were the subjects of recurrent hemorrhagic myringitis, which may perhaps be regarded as corroborative evidence of the general blood vessel weakness.

Suppurative myringitis is more often a primary disease than is sometimes taught, being not very uncommon from various forms of external injury. If the purulent exudation be only superficial, syringing with carbolyzed solution, lightly drying the fundus and slightly dusting with powdered acetanilid, is often sufficient to at once arrest the attack. If interstitial suppuration has occurred the minute abscess should be opened, but only when the whole middle ear is known to be involved is it necessary to cut completely through the drum. While probably the mucous membrane of the tympanum is always congested in suppurative myringitis, it is quite common for cases to at once subside without any discharge from the middle ear or perforation of the drum, even though the swelling of the latter may have been extreme and the external purulent exudation considerable. In a few cases the irrigation and acetanilid may have to be continued for several days, or in rare cases the whole middle ear may become involved and perforation occur; the latter is, however, a most unusual accident under modern treatment.

The object of the writer in this brief sketch has been to call attention to an apparent want in modern otologic literature, and to further specialize the somewhat too generally treated subject of acute otitis. The classification suggested is believed to be new, and to be founded upon perfectly definite pathologic facts.

213 South Seventeenth Street.

DISCUSSION.

DR. HERMAN KNAPP—In some cases I have not been sure whether myringitis or middle-ear disease existed. Such are the cases where after sea-bathing there is earache, and on looking into the ear we find that the drumhead is softened and reddened, as is also the adjacent portion of the canal. For treatment I have advised rest for several days, with the result that the redness has disappeared without any other treatment. I think that parasitic myringitis should come under this head. It occurs almost exclusively in the drumhead and is not very frequent. It is remarkable that these cases of parasitic myringitis occur more often among the wealthy than the poor. I have treated these cases successfully by 4 per cent. of salicylic acid in alcohol. If this is put into the ear three times a day the parasite is very soon destroyed. I have used the same solution also in parasitic troubles of the throat.

DR. HEFFNER—Is there any irritation from the instillations of alcohol?

DR. KNAPP—As I have used it, it does not produce any irritation, and cures these cases more quickly than any other remedy.

DR. J. A. STUCKY—I am disappointed in the treatment of these troubles of the membrana tympani with the Politzer bag and syringe. The bag should be used cautiously, if at all. I question the use of large quantities of water in cleaning the canal. It rather increases than diminishes the pain. Patients will endure gentle syringing to the extent of two or three ounces of water very well, but it should not be carried to the point of dizziness or discomfort. I have the best results from keeping the patient in the recumbent position for a day or two. Where this could not be done I have had excellent results by administering salicylate of soda in 0.65 gram doses, every two or three hours, and applying locally 10 per cent. of

cocain and resorcin in aqueous solution. The action of the cocain is intensified and prolonged by the resorcin and rendered more readily absorbed.

Dr. SCHEPPEGRELL—As to parasitic myringitis being more a disease of the wealthy than of the poor, my experience has been to the contrary. In hospital work I find many cases, but in private practice they are very rare.

Dr. FREEMAN—Under what head does Dr. Seiss place these cases of myringitis where there is a form of bleb on the membrane?

Dr. SEISS—Hemorrhagic. As to the pain of syringing, I have a large clinic with eight assistants, and when these cases come in two of these assistants attend to them. These two gentlemen can use a syringe with a quart of solution and give relief to the patients; my other six assistants will make the ears of the patients ache. The way the syringe is handled makes the difference. As to the use of cocain, the general surgeon and the ophthalmologist have decided that even moderate solutions in inflammatory conditions are wrong. To use it in active inflammation has made these cases worse.

ACUTE AND CHRONIC CARIES AND NECROSIS OF THE MASTOID; PACHYMENINGITIS EXTERNA; EPIDURAL ABSCESS.

Presented to the Section on Laryngology and Otology, at the Forty-eighth Annual Meeting of the American Medical Association held at Philadelphia, Pa., June 1-4, 1897.

BY HERMAN KNAPP, M.D.

NEW YORK, N. Y.

Of all the ear diseases, I know none that are, on the one hand, so important and dangerous, and on the other, so gratifying and manageable as the group comprehended in the title of this communication. If left alone they prove fatal in a large percentage of cases; if treated understandingly, they nearly all recover. The grippe has made us familiar with acute mastoid caries. In the first or second week of an attack of acute otitis media there is intense pain in ear and head; tympanic membrane red and bulging; in a few days otorrhea, with or without paracentesis of the drumhead; relief of pain for a few days, then return of it with tenderness and swelling of the mastoid, membrana tympani bulging in upper-posterior part, slight fever, loss of appetite, headache, mental depression; hearing greatly impaired. The further course varies greatly. The discharge may be free for a time, then diminish and disappear together with the other symptoms—natural recovery in the first stage. Or the swelling over the mastoid and the other symptoms become more pronounced, the outer table of the bone is perforated, a post-aural abscess forms, breaks, and the patient gets well—recovery in the second stage.

In the third stage a perforation through the medial table takes place, either outside the skull into the digastric fossa, or into the cranial cavity, more frequently the posterior cranial fossa than the middle. Exceptionally the pus travels through the fenestræ into the inner ear and farther through the internal auditory meatus into the cerebellar cavity. The two varieties are frequently combined and terminate fatally by meningitis and sinus thrombosis, rarely by abscess.

After this brief sketch I will illustrate the chief features of the affection by abstracts of some case histories.

Case 1.—Tympano-mastoiditis from grippe. Acute caries of the mastoid. Extensive operation. Rapid and perfect recovery. End of February, 1896, Mr. G. A. St., a healthy, strong man, was attacked with grippe. In the second week, ear and headache; paracentesis of drumhead; copious otorrhea; relief for a few days. Then symptoms were aggravated; fever; no particular swelling of upper-posterior end of ear

canal; drumhead white, moist, perforated. Mastoid slightly swollen and tender, particularly at the tip and posterior border. Gland over the tip swollen. Temperature 100.2 degrees; pulse 64. Two days later symptoms more pronounced; posterior upper part of canal slightly bulging.

Operation under ether. Large incision down to bone from tip to above the auricle; periosteum scraped aside; bone over antrum discolored. Chiseling at the antrum pit soon gave vent to thin pus. The interior of the mastoid was one mass of brittle bone, pus and granulation tissue. The outer table and the whole tip removed, laying bare the digastric fossa. The head of the muscle was not infiltrated. The mastoid cavity was most carefully scraped with sharp spoon, until the wall appeared clean and glistening. The inner table was not corroded, the operation being done as early as seven or eight days after the onset of the ear affection. The patient's neck felt stiff for a few days, after that he made a rapid and complete recovery, with hearing as good as before, and with a surprisingly small indrawn scar.

The most remarkable feature in this case is the rapid destruction of the interior of the mastoid and the caries of the whole tip, tables and interior. The total removal of the tip in such cases is the best guarantee of a quick, undisturbed and permanent recovery. If the tip is left, the improvement after the operation is only temporary; relapses with headache and other ominous cerebral symptoms are apt to follow until the tip is removed. This was exemplified by a case I published several years ago, and, I fear, by a recent case which terminated fatally. Its history is as follows:

Case 2.—Acute tympano-mastoiditis. Extensive caries. Recovery delayed until necrosed tip was removed. Well three months, then died of typhoid fever. Frank Steinbrugg, aged 59, contracted a cold, end of March, 1896; ear and headache; paracentesis; otorrhea. First seen May 4, 1896. Upper-posterior part depressed; mastoid tender and swollen.

Operation. Large opening of mastoid, striking pus in a depth of three millimeters, through ivory-like hard bone over antrum. Extensive cavity filled with brittle bone, pus and granulation tissue, which was cleanly removed. Left hospital in twelve days; treated at office, occasionally. Went to business. At the last visit he paid me, about two months after the operation, the remnant of the tip of the mastoid was necrosed, yet still immovable. His family physician extracted it a few days later. Patient felt well for three months; attended over-zealously to his business, and died of what his family physician declared to be a case of typhoid fever. I have no reason to doubt this diagnosis, yet the differential diagnosis between typhoid fever and the intracranial complications of mastoid empyema is not always easy.

Case 3.—Acute tympano-mastoiditis, not operated on. Death from epidural abscess and meningitis. In the *Archives of Otology*, 1895, p. 263, I published a similar case under the title: "A healthy man, of 44 years, had an acute purulent otitis media, after the grippe. Under treatment with paracentesis and topical remedies, rapid improvement, so that he resumed his business (piano-teaching). Relapse of otitis with severe cerebral symptoms; no operation; death. Autopsy: suppurative of mastoid, with perforation into posterior cranial and digastric fossæ; meningitis." Two days before the patient's death, the family physician told me that two weeks previously the patient had had great pain in his left ear and head; was unconscious four days; then dragged his right leg; let fall things held with his right hand, and could not speak. Then there was a complete intermission, during which I saw him. He had had similar attacks, with convulsions, before he contracted his ear trouble, and his father had suffered from the same disease. His younger brother was a drunkard and died a few years previously, and our patient also indulged freely. This family history and the complete intermission might well have clouded the diagnosis, yet I felt so sure of the aural origin of the brain symptoms that I told the physician that I had the greatest misgivings, and that an operation should be done as soon as there was the slightest aggravation of the symptoms. The second night there was a sudden, rapid relapse and the patient died in twenty-four hours. We made an autopsy in the afternoon of the same day. The very instructive, well-preserved specimen of the temporal bone shows a small Bezold perforation and a large perforation of the medial table of the mastoid process, through both of

which the pus from the mastoid had made its way into the digastric fossa and the cranial cavity, inducing meningitis, the immediate cause of death.

These cases may suffice to support my statement that acute caries of the mastoid is an important and, if left alone, a dangerous disease. Let me now prove by actual experience that it is a manageable affection. This I shall endeavor to demonstrate by examples in which the onward course of the disease was stopped by the hand of the surgeon.

Case 4.—Acute caries of mastoid, pachymeningitis. Operation. Recovery. Annie Parker, 35 years old, came to me January 6, 1897. Acute purulent otitis media R.; the usual symptoms; temperature 101 to 102 degrees; mastoid tender, especially at tip and posterior border.

Operation. Large opening of the mastoid; outer table removed. The whole cavity, filled with pus, decaying bone and granulations, was cleansed. The medial table, soft, brittle, and granulating, was removed, laying bare the pulsating dura and sigmoid sinus (perisinuitis). Communication with the tympanum was established. Speedy and complete recovery.

Case 5.—Acute mastoid empyema perisinuitis with cerebral symptoms. Operation. Recovery. Louise Lefebvre, age 25. Came to clinic March 7, 1897. *Operation:* Incision the whole length of mastoid: large opening down into the tip; pus, brittle bone, and granulation tissue removed. After the scraping-off of the granulations the lateral sinus lay bare one and one fourth inch in length; healthy and pulsating. Rapid and complete recovery.

These observations which I have only sketched, may suffice to show how beneficial thorough operations in these cases may be. Thorough, means the removal of all dead material, pus, carious and necrosed bone, and granulation tissue, the constant accompaniment of dead tissue, especially bone. Care must be taken in doing these operations not to injure the lateral sinus, which accident has happened to me five times. It may happen with the chisel, especially one that has sharp angles, but also with a sharp spoon. The accident is mostly without serious consequences, but there are some fatal cases on record (for instance, Kuhn, by entrance of air, Milligan, after an exploratory operation).

Case 6.—Operated on five years ago for mastoid disease. Pain and tenderness in mastoid. Opening. No pus. Injury of sinus. Recovery. Becky Liebermann, came to me March 26, 1897. Five years ago, was operated on in Vienna. Has of late suffered considerably from pain starting from mastoid. Tenderness on pressure, especially on posterior border. No discharge. No swelling or redness of mastoid. Diagnosis: mastoid neuralgia from ossifying mastoiditis. Opening of mastoid: careful chiseling of the hardened and exceedingly vascular mastoid. Finding no pus, I chiseled backward toward the sinus. In scraping the inner table, suddenly a large stream of dark red blood escaped. The wound was tamponed and dressed. The patient made an undisturbed recovery and has lost her pain.

Case 7.—Acute mastoid caries. Pachymeningitis externa. Operation. Recovery. L. Mandelstein, age 50, came to me May 21, 1897. Earache followed by discharge in a few days, ten days ago; mastoid region gradually swollen: doughy, soft over antrum pit.

Operation: Incision from tip to base; the bone, stripped of periosteum, was blackish in the antrum region, from which place pus escaped. Large opening into outer table and tip: very careful scraping removed all dead tissue; the walls of the cavity were hard and shining everywhere except straight backward, where on palpation soft tissue only could be detected. The soft tissue consisted of rather hardened granulations. With the sharp spoon the latter were removed gradually and a gap exposed in the inner mastoid table, which was bordered with the pinkish-white dura mater. Although the dura filled the gap it was possible with the sharp spoon to remove all granulations from it without injury. The wound was tamponed as usual, and May 21, the patient left the hospital to be treated as an out-patient.

In some cases the cerebral symptoms complicating middle-ear disease are so marked that we have to

abide by our diagnosis, although on opening the mastoid we find neither pus nor a fistula to guide us. In such cases we should make an exploratory opening into the cranial cavity. In support of this proposition I will briefly relate a case which I detailed at the meeting of the American Otological Society in 1896.¹

Case 8.—Mastoiditis, epidural abscess, beginning leptomeningitis. Opening of mastoid and cranium. Recovery. Mrs. J., age 52. Chill May 4, temperature, 103 degrees; pulse 106. May 13, chill; severe pain in left ear; great dizziness; temperature 104 degrees; drumhead red and bulging; serous oozing from ear; relief. May 16, discharge suddenly stopped; pulse 84; temperature 103 degrees; projectile vomiting. May 26, nausea, vomiting, delirium; discharge suddenly stopped again; mastoid tender. May 27, cerebral symptoms more pronounced: 6 p.m. decided delirium; great pain in ear; tenderness of mastoid; vomited several times; irrational: muttering delirium.

Operation at 6:30 p.m., ether. I penetrated into the antrum, then the tip; cells lined with thickened mucous membrane; no pus; bone substance very vascular, soft and brittle. The dura mater of the posterior cranial fossa was laid bare two cm. in diameter. No pus being found, I exposed a small patch (7 mm. in diameter) of healthy looking dura mater at the base of the middle cranial fossa, by chiseling forward and upward, directly behind the attic. Then I chiseled from the antrum straight inward and slightly upward, till the probe penetrated into the attic. No pus anywhere, nor a fistula to guide us. Having in this way opened all the cavities which in suppurative inflammations are most liable to transfer infective material into the cranial cavity, I stopped. The patient rapidly improved. Two days after the operation the family physician who conducted the after treatment, found the dressing soiled with abundant, foul smelling, slightly greenish, purulent secretion which filled the wound completely. This secretion, which in other cases also has been observed to make its appearance one or several days after the operation, must have originated in an epidural abscess, and beginning leptomeningitis.² The patient made an uninterrupted and permanent recovery.

What ravages chronic caries and necrosis in the temporal bone may work, can be seen in a specimen which I exhibit. The whole mastoid and the external half of the petrous bone are honey-combed with caries. The disease must have lasted a long time, with free exit of pus outwardly. I have operated on several persons who had this condition and recovered. In the winter of 1896-7 I operated on a scrofulous child whose ear was in the same condition.

Case 9.—Extensive chronic caries and necrosis in the left temporal bone (the petrous portion included) of a scrofulous girl. Pachymeningitis. Perisinuitis. Operation. Recovery. Flossie Heissenbuettel, 3 years old, admitted Nov. 3, 1896. Had measles February 1896; broncho pneumonia: mumps: suppurating glands of neck; empyema; caries and necrosis of mastoid; fistula. Offensive discharge from left ear; mastoid swollen; fistula in which dead bone is visible. Scrofulous glands of neck discharging pus from long fistulae.

Operation.—Ether: incision from tip up beyond base; periosteum scraped off; dead bone, pus and granulation tissue removed; chiseled the whole osseous wall away, removing all necrosed bone and granulations; at the posterior wall dense, dark granulation tissue, which was carefully removed with a spoon: the dura mater and sinus were extensively laid bare: above and behind the external auditory canal a large mass of carious bone, cheesy pus, and granulation tissue was scooped out: the attic and atrium were gently but carefully scraped till ear-canal, middle-ear, mastoid and adjacent parts of the petrous bone were converted into one large cavity. The child stood the operation well. The ear and glands were dressed with gauze daily for five months, after that more rarely, now every three weeks. There is scarcely any discharge; the cavity is conspicuous, though not half the size as when she was operated upon; it is nicely cuticized; the child has wonderfully improved in general health and can now, seven months after the operation, be considered cured.

¹ See, Trans. Am. Otol. Soc., Vol. vi., part III, p. 290.

² In June 1897, the patient presented herself again. She was in perfect health, but completely deaf in that ear, and complained of a tendency to dizziness which accompanied her ear disease and had never left her. I found the drum membrane totally destroyed, the medial wall of the drum cavity consisting of hard glassy bone, with an irregular surface. All this makes it probable that the inner ear was involved in the suppuration, and the pus which escaped two days after the operation, may have come from the petrous bone.

These nine cases, which I selected from my recent practice, constitute a series of progressive, acute and chronic destruction with extension into the cranial cavity. One case which received no surgical treatment, ended in death by epidural abscess, the other cases, in which timely and sufficient operations were performed, recovered.

THREE CASES OF SUPPURATIVE OTITIS MEDIA: SEVERE SYSTEMIC AND REMOTE DISTURBANCES; RECOVERY AFTER MASTOID OPERATION AND REMOVAL OF POLYPI.

Presented to the Section on Laryngology and Otology at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY HIRAM WOODS, JR., M.D.

CLINICAL PROFESSOR OF EYE AND EAR DISEASES, UNIVERSITY OF MARYLAND.
BALTIMORE, MD.

Certain local changes are admitted as indicating need of the mastoid operation. If one or more of the so-called vital indications be present, the demand is emphasized. Apart from these, cases are observed where there is room for legitimate doubt before and after operation; before, because there are no distinctive local signs of pent-up secretion, and yet we see phenomena most easily accounted for by assuming that such a condition exists; after, because no pus is found, and even if the patient recovers, doubt intrudes if operation were really needed to effect cure. The following cases illustrate this fairly well:

Case 1.—John S., age 30, a white laborer, was admitted to the Maryland University Hospital, February 19, 1896. He had been injured the same day by the falling of an embankment. A fractured pelvis was found. He made an uninterrupted recovery for four weeks, when, the evening temperature, normal for three weeks, rose to 102.5 degrees. He had no pain. The next morning, March 11, temperature was 100 degrees. About noon, after a slight chill, there was another rise. Examination did not reveal any cause for the condition observed. During Thursday and Friday the diagnosis of sepsis became clearer, by the occurrence of frequent chilly sensations, fever, increased pulse rate, sweating, loss of appetite, etc. There were no aural symptoms. On Saturday morning the nurse noticed discharge from the right ear. Temperature was 102 degrees; pulse 96. My attention was called to the man about 1 o'clock. There was no history of previous ear disease. I found pus in the canal, large perforation in the lower anterior quadrant of the drum membrane, Eustachian pervious to both the Valsalvan experiment and to Politzerization, and entire absence of pain. The mastoid was neither red, swollen, nor tender. In view of the apparently good drainage from the ear, I decided against operation, believing that it was a case of painless perforation, and the symptoms would now disappear. Treatment consisted in effecting and maintaining cleanliness. For two days, Sunday and Monday, temperature varied from 99 to 101 degrees. Tuesday evening the man had a chill, followed by a temperature of 103.5 degrees, sweat and prostration. Wednesday the same condition persisted, with the addition of a little redness over the tip of the mastoid. The same afternoon, with temperature 102 degrees, pulse 116, I opened the mastoid under chloroform. The cortex was healthy. The cells were deeply injected, but not more than a drop of pus was found though the opening was continued into the tympanic attic, and a stream of water would pass either way from the ear or mastoid to the other. Recovery was immediate and complete. Temperature reached 101 degrees the day following the operation; but this was the only rise, and the man left the hospital well, May 2.

Case 2. On January 9, 1897, I saw Josephine N., 6 years old, in consultation with Dr. Thomas McCormick of Baltimore. The child had recovered from scarlet fever three weeks previously. There was a history of acute right otorrhea in infancy. Early in the late illness pain had appeared in the

right ear, and had been more or less persistent, though not severe. There had been no discharge. Within the past few days, temperature had become high, after several days of freedom from fever. There was some earache; no more than there had been. Temperature was 100 degrees. The appearance of the canal walls and mastoid was normal. In the drumhead there was the scarred perforation of the former attack. There was, however, no evidence of a tympanic inflammation. Heat was applied for two days, and otorrhea, slight in amount, appeared on the morning of January 11. I did not see the child from the 11th to the 14th. The attending physician noted scant discharge; elevation of temperature; unrelieved pain. On the 15th I found the canal walls edematous, so that a view of the drumhead was impossible. A little inoffensive pus was brought out by the cotton pencil. The mastoid was slightly reddened; more, I thought, from heat than any other cause. Temperature was 101 degrees. I thought we had all necessary indications for operation, and so advised. It was declined, and heat, peroxid of hydrogen and syringing continued until the 17th, when, with temperature 101.6 degrees, pulse 130, local conditions unchanged, operation was accepted. After free incision of the edematous canal walls, and the mastoid periosteum, without finding either pus or a carious point in the cortex, the process was opened, and the opening continued into the attic. No pus was found. Pain was relieved at once; temperature fell to normal, and once during convalescence reached 100 degrees. Otorrhea lasted a few days. The ear hears the watch ¹⁸18.

In Case 1 there were septic symptoms for five days, when a painless otorrhea called attention to the ear. In Case 2 there was pain in a formerly diseased ear from the commencement of scarlatina four weeks previous. After some days of normal temperature, fever returned, without increase in the aural symptoms. In both the appearance of otorrhea failed to relieve. Both recovered immediately after the mastoid was opened, and nothing short of this helped. Yet no pus was found, certainly in Case 2, and only a drop, if that, in Case 1. Similar constitutional symptoms occur in the cellulitis of general surgery, and disappear when the infected area is drained, without the presence of pus. The existence of a like primary infection in the mastoids of these patients seems the most plausible explanation of their symptoms.

Case 3.—Prof. Samuel C. Chew of Baltimore, called me in consultation on Nov. 4, 1896, in the case of Mr. P., 27 years of age. For a week Mr. P. had suffered from left frontal headache, with slight elevation of temperature. There was a history of old intermittent otorrhea, and it was to determine a possible connection between the head pain and this, that I was called in. The man was in bed, complaining of agonizing left frontal pain; temperature 100.8; pulse 96. History showed suppurative otitis dating back to infancy. No systematic treatment had ever been employed. Occasionally Mr. P. washed the ear himself. For five years these attacks of headache had occurred. They were described as sudden, severe, prostrating, and lasting from a few hours to several days. The ear was free from pain, and neither tapping nor firm pressure of the mastoid was resented. The canal walls showed nothing abnormal. A little pus, bad smelling, was found in the tympanum. The drumhead was destroyed, the malleus standing out prominently, thickened, while, apparently attached to the posterior tympanic wall, small polypoid masses could be made out. The patient's family would not consent to operation of any kind. From the 4th to the 7th the ear was kept as clean as possible by syringing, and the use of peroxid. There was no increase in the discharge, and little decrease in the pain. Temperature ranged from 99 to 101 degrees. On the afternoon of the 7th the condition grew worse. Pain was agonizing, requiring large doses of morphin to keep the man quiet. I now had doubts concerning the adequacy of any operation about the ear. Pain was absolutely localized in the left frontal region. From the beginning nothing had pointed directly to the ear. Truc, there was a chronic otorrhea, and inspection showed a state of things commonly observed in old suppurating ears; but this was all. That the ear was the primary cause, I had no doubt. That the disturbing factor, whatever it was, had passed beyond the line separating aural from general surgery, I was beginning to believe. Apart from waiting for localizing brain symptoms, two procedures suggested themselves, removal of the polypoid growths, and mastoid operation. I had little faith in the ability of the first to relieve the

symptoms. Not only might the second prove inadequate and leave the patient still in need of cerebral surgery, but such meager indications as there were, pointed to the front, rather than to the rear brain as the seat of disease. I therefore decided to remove the tympanic growths, and if symptoms did not abate, seek a general surgeon's opinion regarding the need of intra cranial exploration. On Sunday morning, 8th, under unsatisfactory cocain anesthesia, I removed the polyps with Buck's curette. Giddiness, profuse sweating, weakness of pulse, and prostration, were the immediate results. Operation was done at 11 A. M., with temperature 99 degrees; pulse 96. At 4 P. M., temperature was 102; highest during illness; pulse 120. During the evening respiration assumed a character strongly suggestive, if not actually, of the "Cheyne-Stokes" variety. At first shallow, it became deeper, and passing again in reverse order, ceased altogether for a few seconds, returning and passing through like a cycle. Pulse rate increased to 140. It looked as though the end was not far off. The ear condition, however, underwent a change. There was a freer discharge of pus. Arrangements were made for operation in the morning, and an early consultation secured with Prof. Tiffany. We found the man still in pain, but his general condition was better than the previous night. Fetid pus discharged freely, and he complained of nausea. Pulse was 76, and temperature 97.2.

Prof. Tiffany expressed the opinion that this sub-normal temperature threw a new doubt into the case. It might mean cerebral abscess. He advised further delay. It proved to be the beginning of convalescence. Within twenty-four hours pain subsided, and the patient was out in a week. Since, the tympanic condition has been treated. In March the ear was dry, and the man apparently as well as ever. There is not much chance of his staying so. Sooner or later he will have another stormy experience. His history indicates that there is a gradual change of some kind going on in his mastoid, probably an accumulation of pus, until a certain point is reached, when the storm breaks. It seems equally clear that there is no organic brain disease. In his case, another attack would call for the mastoid operation, even if it should not be done before; but so remote, and apparently serious condition as existed here, is not, so far as my knowledge goes, a frequent consequence of mastoid stagnation.

DISCUSSION ON PAPERS OF DRS. KNAPP AND WOODS.

Dr. SEISS—Out of my last 4300 cases, only 85 were mastoid. Out of these there was only one death, and that was the only case where any more extensive operation was done than removal of the outer table.

Dr. RANDALL—To know what constitutes disease of the mastoid is essential. Where we have decided swelling, redness and pain over the mastoid region with tenderness to pressure, together with acute inflammation of the middle ear, I call it acute inflammation of the mastoid. I see many cases brought to a successful issue after operation. I have seen quite 100 of these cases every year, and but a small proportion come to operation. I have done as high as thirty mastoid operations in a year, all with pus freely present over the mastoid. In at least one-half of my recent cases the inner table has been broken down, pus was present on the dura, and pachymeningitis more or less present. In the last Stacke operation which I did, I found it impossible to determine where the dura lay. It was covered with flabby granulations, and in removing these with a curette I stopped short because I found I was removing brain tissue. The patient was not hurt by this blunder, so far as I could discover, but it shows that we must be careful. In these cases I can not feel as a general thing that I have done too much. I can not always get complete healing by radical measures, and it is perfectly fitting for those who hold more conservative views to hold them in spite of all that I can say. The majority of mastoid cases can get well without operation and not be in the slightest degree worse for the delay. Last year I had 500 cases; others might say that they were not mastoid cases at all. I can not give only one death in 85 cases, but I have but one death due to operation in 135 cases. One or two died of pneumonia or brain disease, absolutely uninfluenced by the operation.

Dr. WOODS—I am aware that the first two cases I reported

are open to criticism as to whether they would not have done just as well without operation. The knowledge of that fact led me to report them. There were no local symptoms of mastoid disease, save the slight redness mentioned; and yet, with a history of acute otorrhea in the first, old suppurative otitis in the second, and temperature characteristic of sepsis in both, operation seems to me the safest treatment.

Dr. LAURENCE TURNBULL—I would like to ask Dr. Knapp as to neuralgia of the mastoid. I know of a case where a young girl passed a bead into the mastoid. It gave no uneasiness at first, but later there was discharge and pain. She came to the Jefferson Hospital with this peculiar neuralgic pain gravitating toward the mastoid, and after cleansing the ear we opened the mastoid and left the bone clean and white. She seemed to be improving for a time, but later returned several times with the intense pain. The mastoid was finally opened a second time; but she still has the pain.

Dr. KNAPP—I have found mastoid neuralgia in cases where a chronically inflamed mastoid is undergoing conversion from the pneumatic and diploic varieties into the sclerosed. When we operate for this condition we mostly find the mastoid compact and, in some layers at least, usually the medial ones, congested. These cases get well by operation, and in time, also spontaneously, I think by destruction of the nerve either by the operation or by compression during the sclerosing process.

WHAT CAN BE ACCOMPLISHED BY TREATMENT OF EUSTACHIAN TUBE,

WITH SPECIAL CONSIDERATION OF THE TREATMENT OF CHRONIC STENOSIS.

Presented to the Section on Laryngology and Otology, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY GEORGE MORLEY MARSHALL, M.D.

LARYNGOLOGIST AND OTOLOGIST TO ST. JOSEPH'S HOSPITAL;
LARYNGOLOGIST TO PHILADELPHIA HOSPITAL.
PHILADELPHIA, PA.

Let us briefly recall the anatomy and function of the Eustachian tube, in so far as it concerns the measures advocated in this paper. The Eustachian tube is the passage between the naso-pharynx and tympanic cavity—in length thirty-three to forty millimeters. From its relatively large pharyngeal mouth it extends twenty-five millimeters with walls formed by an incomplete furrow of fibro-cartilage, consisting of a posterior and anterior plate, the anterior being movable. This portion of the tube where not cartilaginous is membranous, which with its lining mucous membrane has considerable thickness. This cartilaginous portion of the tube unites with the remaining ten to fifteen millimeters of the osseous portion of the tube, forming with it an obtuse somewhat circular angle of 135 degrees. At this angle the lumen of the tube is smallest; that is two to three millimeters.

The walls of the Eustachian tube are lined by glandular mucous membrane, with ciliated cylindric epithelia, whose ciliary movement is directed toward the pharyngeal opening which has a lower level than the tympanic opening. The lining of the osseous portion is smooth and closely incorporated with the periosteum. With surrounding conditions normal, the normal Eustachian tube allows the passage of air not with absolute freedom, for the tube at rest has its sides in contact, but yet with sufficient freedom to establish an approximate equality of atmospheric equilibrium, allowing the secretions of lining membrane of the tube and tympanum to escape or evaporate. But if atmospheric pressure is not approximately equal the air in the tympanum is absorbed by surrounding liquids through the walls of blood and lymph vessels, obeying the law that liquids absorb their own volume of associated gas, and thus the air not being renewed in the tympanum, there follow the

well-known symptoms deafness, feeling of fullness, a probable tinnitus, autophonia, but especially that decisive sign, the appearance of the retracted tympanic membrane itself.

But with retracted membrane the alert aurist would not, necessarily, diagnose at once an obstructive Eustachian tube, as turgescence or hypertrophy of the turbinated bodies alone might account for the rarefied air to a considerable degree. Still more will the pressure be out of equilibrium if the opening between pharynx and naso-pharynx be occluded.

Two cases presented themselves to me which will illustrate this condition to an extreme degree.

M. S., age 40, had periods of great deafness, and in one such period came to me for relief. The tympanic membranes were strongly retracted, the turbinated bodies were very turgescient, the patient being evidently in the midst of an attack of acute coryza. The communication, in this case between the pharynx and naso-pharynx, was totally shut off by a smooth impervious membrane. The history of this condition was as follows: When a schoolgirl at Heidelberg she was bending over her desk with a long sharpened slate pencil in her mouth, the teacher coming behind to rebuke her for idleness, gave the child a blow upon the head with a book. The head was driven down upon the unyielding pencil, whose other end was supported by the desk. Its point was thus driven into the pharyngeal wall. Although attended by one of the able professors of the university, extensive ulceration occurred and doubtless the final condition failed to be presented to him. At least, her condition had remained from childhood as she presented herself to me. At once, on opening this tough membrane with an instrument I had devised for somewhat similar cases her hearing was restored and she was enabled to blow her nose for the first time in thirty years.

Another case, B. S., 4 years old, had scarlet fever a year previous, resulting in great deafness, which was worse at times of coryza. Adhesion had resulted between the pharyngeal wall and the soft palate, producing complete occlusion of the passage. The child was operated on with the above-mentioned instrument, which aided much in the facility of the operation, as it is extremely difficult to manipulate a cutting instrument back of the palate without danger to the carotid arteries. The hearing at once improved and although the sclerosed tissues at the seat of the old ulceration again closed, the operation was repeated a third time after intervening periods of considerable length, when the opening became permanent.

Many cases of lesser degree of obstruction at this point (the naso-pharyngeal opening), would still have the effect of disturbing the equilibrium of atmospheric pressure in the tympanum, and the above cases are only cited because of the absolute demonstration of the effects of rarefied air in the naso-pharynx. Other lesser impediments, as adenoid growths, which I believe directly arise from a previous nasal obstruction, although possibly a temporary one, and which producing this rarefied condition of atmospheric pressure will, with its continuous, yet slight suction power, so affect the yielding tissues of the infant as to cause venous congestion favorable to the growth of adenoid tissue. Retained secretions, bacterial growth therein and consequent irritation likewise favor the growth of lymphoid tissue, conditions that must also be attributed to nasal and naso-pharyngeal obstruction. Thus I believe this tissue instead of being responsible for venous congestion, as is maintained by prominent authorities, is one of the sequelæ of the congestion. The continued pressure of lymphoid growths also favors the continued congestion and obstruction, and likewise hypertrophies of the turbinated bodies, deflected septi, nasal polypi, and nasal spurs, may interfere with the ingress and egress of air and the resulting equilibrium of atmospheric pressure, and they must therefore be removed by appropriate operation or treatment before attention is directed exclusively to the Eustachian tube.

Now, if obstruction of nasal passages or naso-pharynx produces this want of equilibrium in the tympanum, so much more will stenosis or occlusion of the tube itself, and will lead to that venous congestion of the tympanum which I believe is responsible for a very large majority of cases of chronic tinnitus aurium, as well as chronic deafness resulting from sclerosis of tympanic membrane and associated structures, for not only is the circulation of the blood abnormal, but the reverberating sound waves of the blood currents have no longer their normal exit, but are as in the closed seashell, which confines the sound in unbroken walls. I have noticed this tinnitus to be removed for several days after the relief of the venous congestion following the removal of a nasal spur, with free hemorrhage, and so I could explain the relief after depletive measures, as by catharsis and pilocarpin, which give temporary relief. But the belief that free ingress of air into the tympanum will at least relieve the congestion, and therefore the tinnitus, has been borne upon me, especially during the last two years, by the results of a more systematic use of bougies in the Eustachian tube where stenosis of the tube or retraction of the tympanic membrane existed. I have tabulated a series of thirty cases which had long become chronic and which will therefore be of more interest because of their usually intractable nature. Seventeen were chronic cases of tinnitus and all chronically deaf, with one exception which although marked chronic tinnitus, exhibited no degree of diminished hearing, yet was (I think) in the first stage of venous congestion. After systematic use of bougies the results in these seventeen cases was, seven were made entirely free, five improved to such a degree that it became no longer troublesome, while in five there was no reported change. But, with one exception, those not improved had but few treatments. In two of the favorable cases, although the tinnitus had been constant for six or more years, it was removed only after six months of treatment. In the twenty-nine cases of chronically deaf, one only was restored to normal hearing; seven were very much improved; five slightly improved; one heard better in one ear, but worse in the other, while in nine there was no change. One of these cases was of deafness without tinnitus, which was decidedly improved by the bougie, although the air douche had previously failed to relieve to the same extent; yet in this case there was relapse to nearly the first condition, although bougies were used for quite a year. In no case was there any unfavorable result, unless it were in one case, who six weeks after her last treatment was taken with an acute middle-ear trouble, which soon subsided, but the patient had been perfectly free from pain in the interval, in fact relieved in a degree from deafness, and she attributed the inflammation to a severe cold. I speak of this as a possible sequel, as I have been particularly watchful for any possible bad effects from the use of the bougies. Thirty may seem too small a number of cases from which to draw any sweeping conclusions, yet the good results in these few may have been due to the method used in its performance. Appropriate cases, viz., those with retracted membrane and which are given temporary relief by air douche or massage, should be selected.

My rules are as follows:

1. Never delegate the work to another.
2. Never do it hurriedly (several times I have broken this rule and failure resulted), but always

count upon having, if necessary, one-half hour for the operation. Usually it may be done in a minute or less, but difficult cases arise, but if done leisurely an apparently difficult case becomes easy.

3. Have proper fitting, well-shaped Eustachian catheters. Those from Reiner in Vienna have given me perfect satisfaction.

4. Have antiseptically clean catheters and bougies.

5. Prepare the mucous membrane of the nasal passages, especially the pharyngeal mouth of the Eustachian tube, with an application of a 10 per cent. solution of cocain.

6. Smear the bougie with a 3 per cent. ointment made of lanolin and nitrate of silver. This measure is, as far as I know, original, and to it I attribute largely the good results. Unlike other fats lanolin clings tenaciously to the bougie, shields it and makes its passage more easy; and with the argentum nitrate is antiseptic and alterative in effect locally. I have it prepared from the aqueous solution of silver nitrate so that it becomes a stiff emulsion. It is only after long exposure that the ointment undergoes a chemio change, becoming black on the surface but apparently unchanged beneath.

7. Observe that the bougies are in perfect condition. Celluloid may become brittle and therefore highly dangerous, and whalebone may become rough or thready and therefore irritating.

8. Let the bougie rest in place twenty minutes to half an hour in the Eustachian tube.

9. Use the bougie not oftener than twice per week.

10. Measure the bougie and see that it does not advance more than thirty-three millimeters.

After making sure of nasal and naso-pharyngeal freedom, the above treatment seems a rational one, and directed to the securing of equilibrium of atmospheric pressure in the tympanum. To secure this condition I believe should be the foundation effort. Where equilibrium is wanting, air douching, either by catheter. Politzer's method or otherwise, and massage of the ossicles and membranes, can be but of temporary effect.

The analogy of chronic stenosis of the tear duct and of the male urethra is sufficiently suggestive. It would be a timid surgeon that in stenosis of either of those passages would rely upon applications of a vapor or a liquid. If gradual dilatation in those passages is indicated and an accepted measure, I believe it to be in the Eustachian tube. That stenosis may at some time return is no argument that the treatment should not be adopted, but because of the delicate nature of the Eustachian tube it should never be treated by careless or unskilled hands.

1819 Spruce Street.

NATURAL GAS AND EUSTACHIAN INFLAMMATION.

Presented to the Section on Laryngology and Otolgoy at the Forty-eighth Annual Meeting of the American Medical Association held at Philadelphia, June 1-4, 1897.

BY JOHN JOHNSON KYLE, M.D.

MARION, IND.

Some few weeks ago it was my pleasure to read a paper before the Western Ophthalmological, Otolgical, Laryngological and Rhinological Association, calling attention to the effect of natural gas upon the conjunctiva. I now desire, in a general way, to show wherein the natural gas from the Indiana field is a

potent factor in causing catarrhal inflammation of the whole pneumatic system, with special reference to the Eustachian tube.

The gas from Indiana differs from that of the New York or Pennsylvania field, in that it contains sulphuretted hydrogen, and in burning the process of combustion is not so complete. Eighty-five per cent. of the natural gas is marsh gas, which is composed of 75 per cent. by weight of carbon and 25 per cent. of hydrogen. The products of combustion, which differ in every case, are carbon dioxid, water vapor, sulphur dioxid, trioxid, nitrogen oxids and ammonia sulphate. The sulphur oxids soon became sulphuric acid, collecting as such upon chandeliers and smoke shades. As a result of the combustion, the greatest irritant to the mucous membrane is produced. This is more noticeable in winter than in summer, and results from imperfect ventilation, thus allowing excessive accumulation of burnt gas, which is constantly thrown off from jets, open fires and stoves. In consequence we have a marked increase of nose, throat and bronchial affections.

The Indiana gas belt covers a territory of 2500 square miles, with a very large population made up of immigrants and foreigners. Where jets are used for illuminating, patients suffering from phthisis, hay fever, asthma, catarrhal pneumonia, diphtheria and scarlet fever, especially suffer from this irritation. Where every effort is made to subdue abnormal cough or throat irritation the substitution of lamps brings relief. The gas is very destructive to carpets, draperies, gold and silverware and surgical instruments. Public speakers, actors, singers, and especially those who are accustomed to moist sea air suffer from this poison.

We consider systemic diseases, climatic conditions, unhygienic surroundings, malarial poisoning, sewer gas and etc., causes of middle ear diseases, and that inflammation of the Eustachian tube is an extension of a diseased condition of the nose and throat. The tissues of the tube are virtually the same as those of the throat, containing lymphatics, a plexus of nerve fibers and nerve cells: within the stroma of the cartilage are numerous mucous glands lessening as we reach the osseous portion. The tube is covered with ciliated epithelium, which are in constant motion, moving like fields of grain. The glandular system of the tube plays the important part in acute inflammation due to natural gas, coincident with similar change in nose and throat. In the prodromal stage all victims suffer more or less alike, complaining of dryness and fulness of nose and throat. The sensation of dryness is not unlike that from cocain anesthesia. If exposed to burnt gas with this we have huskiness of voice and an exceedingly annoying cough. Within twenty-four to thirty-six hours the inflammatory stage, differing in every case, is ushered in by slight elevation of temperature, general malaise, tinnitus aurium and headache. If apartments are illuminated with jets we will have constant cough from the sulphur oxids, and an abnormal desire for sleep, which results from excessive inhalation of carbonic acid gas. On examination in acute cases, we find the mucous membrane of the nose and throat swollen and of a dry glistening appearance. The dryness is so excessive as to cause the mucous membrane of the cartilaginous septum, throat and gums to crack open, which allows exudation of the fluid elements of the blood. This dries in the form of bloody crusts along the septum and is with difficulty

removed, reforming, however, very rapidly. The accumulation of thick mucus tinged with blood is excessive in the vault of the pharynx.

With the exception of the vestibule, it is asserted that the nose and throat is an aseptic cavity! Hugen-schmidt (*Annales de l'Institut Pasteur*) asserts that "in the pharynx there are true lymphatic sacs containing various kinds of phagocytes under the epithelial layer, which are constantly being passed on to the mucous surface between the epithelial layer." The gas destructive to the epithelial covering of the pharynx and to that of the anterior septum, most naturally perverts the function of the leucocytes; thus readjustment of the tissues may be slow on account of the constant reinfection.

The tendency of patients in acute cases, due to the swollen and inflamed condition of the nose, is to breathe through the mouth during sleep. As a result of the lessened chemostatic power of the saliva during sleep, we have with the marked local effect in the oral cavity and especially in the throat, elevation of temperature and general malaise, following the invasion of bacteria. The tube when affected, on account of the venous congestion, is swollen and filled with viscid secretion, which is demonstrated by the peculiar sound caused by the current of air being forced into the ear, as in acute cases from colds, etc. Dilatation is not easily accomplished, since on account of the venous congestion, we are compelled to rely solely upon the Politzer method. In cases involving the middle ear, patient complains of fulness, slight diminution of hearing and pain extending to middle ear. We find this especially conspicuous in glass blowers suffering from the disease. On examination we find the drum hyperemic along the short process and handle and always retracted, due evidently to the swollen condition of the cartilaginous portion of the tube. The ear symptoms are not those typically of acute catarrhal inflammation, rather those of the sub-acute form. In from five to six weeks the acute inflammatory symptoms gradually disappear and tissues become readjusted, further proof of the singular function of the adaptation of the mucous membrane to irritating cases. The disease is, however, passive in character and may develop rapidly into chronic inflammation. Chronic catarrhal deafness is such a prevalent disease that it is purely hypothetical to say that natural gas, or any other gas to which the patient is exposed, may alone cause the disease, though we are safe in concluding that in a patient susceptible to such a disease, all the symptoms will be aggravated. In the cases attributed to natural gas the disease was in no wise dependent upon the hypertrophic change in the nose, but upon the diseased condition of the pharynx. The ease with which patency of the tube and mobility of the drum are restored differentiates it, I believe, from so-called catarrhal deafness. The mucous membrane of the anterior septum will in chronic cases be found covered with superficial blood vessels and crusts, which cause frequent septal hemorrhages, a condition closely allied to rhinitis sicca anterior, a disease first described by Siebemann in 1889. The throat symptoms now resemble chronic pharyngitis or clergyman's sore throat, membranes more or less covered with follicles varying in shape and color; superficial veins always in great numbers; the secretion from posterior nares thick and tenacious. In the acute stage the treatment is necessarily palliative and sedative. Unless in the treat-

electric lights substituted, little result is secured. The mucous membrane of the nose and throat is cleansed with Seiler's or Dobell's solution, followed by a spray of albolin, menthol and camphor solution. In the treatment of tubal and middle ear affections we rely upon the inflation with the Politzer method, condemning the canula and relying upon hot applications and massage, which relieves the congestion and promotes the absorption of any serous exudation within the middle ear. Frequently a change of surroundings is absolutely necessary, as no other form of treatment brings relief. The acute stage usually passes off quickly, and prophylactic and palliative treatment is all that is necessary.

In the chronic stage the treatment of the pharynx with its enlarged follicles and superficial veins, our absolute reliance is upon the galvano-cantery. The stenosis of the Eustachian tube is treated by inflation through a No. 2 or 3 German silver canula with injections of, preferably, menthol camphor in albolin, and massage the drum. The septal hemorrhage from the crust formation and habit of picking the nose, is relieved by the destruction of the superficial blood vessels with the actual cautery or strong solution of nitrate of silver. The crusts are softened, and healing stimulated by yellow oxid of mercury ointment or ichthyol, 3 per cent. in lanolin.

The normal ciliated epithelium is now replaced by cicatricial tissue. In conclusion we assert:

1. Natural gas is an important factor in relation to public health.
2. The elements of combustion are active irritants to the exposed mucous membrane.
3. It is an exciting cause of catarrhal inflammation of the nose, throat and middle ear.

TINNITUS IN ITS RELATION TO NASAL AND AURAL AFFECTIONS.

Discussion in the Section on Laryngology and Otology, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

OPENED BY B. ALEXANDER RANDALL, M.D.

PHILADELPHIA, PA.

This is a topic which appeals to all of us and it is important that clear views should be obtained of it so far as possible. The division into the objective and subjective forms is hardly worth mentioning, and yet we should remember that there is a large amount of objective tinnitus present in aneurysm, etc. Several cases bring clearly to my mind how easy it is to ignore this matter. It is inevitable that we should have a large bruit ever present, and if an anemic condition gives rise to anemic heart-sounds it may result in similar murmurs in the ear.

It is important in turning to the subjective symptoms, to remember that there are at least five points where this condition may arise, marking the cerebral, the labyrinthine, the tympanic, the tubal and the purely nasal forms. With this distinction it is clear that we are all interested in the question of what we generally call aural tinnitus. The conditions are largely vascular and there may be a local lesion which determines the exact exciting cause. It is of wide spread character, and I suppose there are few who are more prone to tinnitus than the overworked physician. We will find that the proper use of rest, or some of those substitutes that we employ such as strychnia, will be

these conditions, where there is vasomotor trouble, than the bromids and sedatives. As to the labyrinthine cases we must guess rather than speak with certainty. The tympanic cases are many, and the effect of pneumatic massage will promptly demonstrate that the trouble is located in the tympanic cavity. A little mobilization will account for much of the trouble and give great relief. In all cases I use the pneumatic massage to a great extent. I employ finger-tip massage in this way: Instead of using the mere pressure, I insert the finger into the auditory canal as deeply as possible, and then with a piston movement I can secure a decided amount of suction as well as pressure. This measure I have found harmless as far as tested, and it is always within the power of the patient. I have often found it very effective. In these cases, tubal or otherwise, where we have to resort to other measures, it is often possible that with the best employment of those measures we get only moderate relief, which is for a time trebled or quadrupled by the pneumatic massage.

The manner of tubal relief has been discussed by Dr. Marshall, and I cordially accord with what he has said. Great relief can be had with the use of the bougie, but it is so delicate a procedure that I employ it very little, especially in the dispensary. The employment of silver followed by the vapor of iodine in the tube, is also valuable. It is certainly a potent method, potent for evil as well as good, and should be used with the greatest caution. The element of pressure is an essential and valuable factor in many cases.

The nasal causation of tinnitus is well known. It is well to remember that these are complex matters, and that in some cases the incautious cauterization of the turbinal has been followed by intracranial thrombosis.

Dr. MARTINDALE—In a large number of cases you will find that you are dealing with objective instead of subjective tinnitus. We have tinnitus because there is a slight and often unrecognized lesion in the middle ear or the Eustachian tube, which is sufficient to determine the symptoms to that point rather than to the eye or some other organ. As to the value of the otoscope, I have given up its use almost altogether. It does relieve tinnitus for a short time, but it comes back. I am glad to learn that the results are sometimes permanent. I do think that harm can be done to the canal by the inflammation. Passive motion of the ossicular chain will cause the condition to increase. If the patient is suffering from progressive inflammation, this treatment is like trying to walk with a sprained ankle. If you increase the blood supply by inserting the finger into the canal and manipulating the parts, it may cause an increase of the trouble.

I use the Eustachian bougie a great deal and do not think it is dangerous. I employ a very simple form of instrument made by taking a No. 5 piano wire and bending a hook in one end. This is passed through a Eustachian catheter, and will protrude from the mouth of the catheter about an inch and a half. Wrap the hook with sterilized cotton, to any size you please, according to the amount of stenosis. The advantage is that the cotton can not slip off, and that carried rapidly through the tube into the stricture and allowed to remain a few moments, the cotton increases in size, and you have increased dilatation. You avoid the friction of celluloid, whalebone or other bougies in passing through the cavity. When

continue with great caution. I have used silver, but not for a long time. Nasal tinnitus is often due to labyrinthine conditions.

Dr. MAX THORNER—Often cases of tinnitus aurium have suddenly disappeared after the removal of obstructions in the nasal passages, but we can not promise relief in all cases. I have seen cases where the nose was perfectly normal, with very little trouble in the naso-pharynx or the Eustachian tube. In such cases the result of any treatment depends entirely upon the intra-aural condition. The worst cases are those where we have sclerosis in the middle ear and a patulous tube.

I have removed the ossicles and made multiple incision through the drumhead as recommended a number of years ago, and have seen occasionally some improvement, but this did not last more than two, three or four months. I have used the pressure probe of Lucae, and have given treatment by the exhaustion of air, but no more than temporary improvement has followed in the majority of cases. I have found inflation of temporary benefit. If we would examine in every case, we might find adenoids, or nests of adenoids in a large number, although their removal does not always cure the tinnitus. I have used iodid of ethyl in acute and chronic cases; and frequently have found it give relief, where nothing else would benefit the patient even temporarily.

Dr. MARTINDALE—One objection to the cotton plug is that it only touches one point of stenosis. If an attempt is made to make pressure to a considerable extent, it is hard to get an equal caliber. I also believe that cotton is more irritating than the smooth surfaces of celluloid or whalebone. We need only compare it to the use of the steel sound in the urethra; no matter how small the sound, we find that cotton is more irritating.

THE SURGICAL TREATMENT OF ACUTE INFLAMMATIONS OF THE MIDDLE EAR.

Presented to the Section on Laryngology and Otology at the Forty-eighth Annual Meeting of the American Medical Association held at Philadelphia, Pa., June 1-4, 1897.

BY EDWARD B. DENCH, M.D.

Professor of Otology, Bellevue Hospital Medical College; Consulting Otologist to St. Luke's Hospital; Attending Aural Surgeon, New York Eye and Ear Infirmary; Fellow of the American Otological Society, of the New York Otological Society.

NEW YORK, N. Y.

Up to a comparatively recent date an acute inflammatory process within the tympanum was scarcely considered worthy of consideration, from a surgical point of view, unless it was of so severe a type as to involve the osseous structures in immediate relation with the tympanum. The general practitioner, and quite frequently the otologist, advised what was then the "conservative treatment" of these cases. The patient was allowed to suffer pain until spontaneous evacuation of the inflammatory products occurred.

It is hardly necessary for me to point out that this plan was erroneous. It was, perhaps, excusable for the reason that only within the last few years has much been written upon the special anatomy of the middle ear. Thanks to the investigations of Blake and Bryant of Boston we no longer consider the middle ear as a single cavity, but divide it into two portions, the atrium and the vault, by a horizontal line drawn through the short process of the malleus, the

it. On account of this division, we recognize two forms of inflammation of the middle ear, one affecting primarily the atrium, and the other the vault of the tympanum. An inflammation of the atrium is characterized by symptoms common to a catarrhal inflammation in any other portion of the body, that is by an effusion of a fluid. This is due both to an increased quantity of normal secretion from the glandular structures and also to a serous transudation from the blood vessels. Owing to the small amount of connective tissue within this space, suppurative inflammation is practically impossible. On the other hand, an inflammation in the tympanic vault invariably leads to connective tissue necrosis and the formation of pus. The process follows exactly the same course as an inflammation involving connective tissue in any other portion of the body; that is, it constitutes a true cellulitis. The proximity of the tympanic vault to the mastoid antrum, of which it really forms a continuation, and to the middle cranial fossa, from which it is separated by a thin lamella of bone, renders it evident that a purulent inflammation within this space is always a condition of considerable gravity.

I would not have it understood that a purulent discharge from the middle ear can only result from infection of the tympanic vault. In an acute catarrhal otitis, with rupture of the membrana tympani, the discharge which at first is muco-serous in character, is easily infected if allowed to remain in the external auditory canal, and in this way may become purulent. In this event subsequent infection of the vault of the tympanum is common, but is not the invariable rule. The parts within the upper portion of the middle ear may also suffer from an acute congestion. If the inflammatory process extends no further a certain amount of serous transudation will drain along the long process of the incus into the atrium. In this way the engorged vessels are relieved and suppuration and tissue necrosis is avoided.

An acute catarrhal otitis is characterized by a uniform injection of the entire drum membrane. While the membrana flaccida is red and turgid, the entire membrana tensa is also reddened. If the process has continued for a few hours the posterior portion of the membrana tensa will bulge into the canal, particularly in the posterior segment. In direct contrast with this is the otoscopic appearance presented by an inflammation of the tympanic vault. In the very early stages the membrana flaccida appears greatly reddened and swollen, while the membrana tensa remains perfectly normal in color. Only rarely do we find the vessels of the manubrial plexus slightly engorged. After a few hours the upper and posterior portion of the drum membrane appears to sink downward into the canal, so as to narrow the fundus and partially obscure and hide the upper part of the membrana tensa, the portion of this structure visible still preserving its normal color. In the severe cases the displacement of the upper portion of the drum membrane, that is, of the membrana flaccida, may be so extensive as to allow a view of the lower and anterior segment of the membrana tensa only, this appearing bright and glistening and showing no evidence of inflammation.

The treatment of these conditions differs in that, while an acute catarrhal inflammation may be frequently aborted by local blood-letting in the early stages or relieved by surgical measures, if seen later, operative treatment is imperative, even in the incipi-

ency of an inflammation of the tympanic vault. For a number of years I made an attempt to abort both forms of the disease by local blood-letting, either by means of the natural or artificial leech. At the present time I seldom resort to either of these methods, and am more and more convinced that the only safety lies in making a free incision into the inflamed tissues. If the case is one of acute catarrhal otitis where the membrana tensa is involved, except in the very earliest stage, I incise not only the membrana tympani but the tissue covering the internal tympanic wall in order to secure a complete depletion of the engorged vessels. I am not speaking of cases in which there has been an effusion of fluid into the tympanum. Here, there is no doubt as to the advisability of incision. But even before this has occurred better results will be obtained by the free use of the knife than by any milder measure. In the catarrhal form of the disease this incision should lie in the posterior segment of the drum membrane, close to its periphery, and should extend from just above the inferior pole upward to the posterior fold. As the puncture is made the knife should be carried inward until its point impinges upon the bony wall of the middle ear. It should then be carried rapidly upward to just below the posterior fold. In this way the drum membrane is freely incised for about one-fourth of its circumference. As the upward cut is made care should be taken to keep the point of the knife against the internal tympanic wall, so as to incise the overlying mucous membrane.

In the severe form of the middle ear inflammation the knife should be directed upward, backward and inward, the puncture being made just behind the short process of the malleus. The incision is then carried backward to the periphery of the bony ring, care being taken to divide the reduplications of the mucous membrane filling the tympanic vault. As the edge of the knife touches the bony ring it should be turned upward and the instrument withdrawn, the knife being kept in contact with the bone so as to incise the periosteum of the upper wall of the canal for a considerable distance. By making first a horizontal and then a vertical incision, a triangular flap is formed, allowing free drainage from the tympanic vault. Copious hemorrhage immediately follows the incision and may continue for several minutes. Frequently, after the hemorrhage has ceased, there will be a sero-sanguinolent discharge for one or two days, until the engorged vessels have unloaded themselves and resumed their normal tone. Suppuration is thus prevented, and extension to the mastoid process seldom occurs.

While the incision of the drum membrane is an operation of no great importance, a certain amount of care must be taken in performing this simple procedure. In the first place, it is absolutely necessary that the canal and membrana tympani should be thoroughly sterilized before operation. The field of operation can be rendered almost absolutely aseptic if the canal is first syringed with a warm solution of bichlorid of mercury, 1-5000. The parts are then dried with a pledget of sterilized cotton, and the walls of the meatus and the drum membrane are mopped thoroughly and as vigorously as possible by means of the cotton pledget, with an alcoholic solution of the same drug, 1-3000. As the strong alcohol of the pharmacopoeia causes considerable pain when applied to the inflamed drum membrane, I usually make this solution as follows: one part of an aqueous solution of bichlorid of

mercury (1-1000) is diluted with twice its volume of alcohol. I have found that the desired asepsis can be secured by the use of this mixture, and that the pain consequent upon its application is slight.

No instrument should be introduced into the canal before it has been perfectly sterilized. This is best effected by boiling the specula, cotton holders, forceps, etc., in a 2 per cent. solution of sodium carbonate. As prolonged boiling takes the "temper" out of the delicate knives used in the operation, these should be immersed in the fluid only a short time, one minute being usually sufficient, if they have been thoroughly cleansed mechanically, before being subjected to boiling. The cotton used should also be surgically clean. Of late, I have adopted the following plan for the sterilization of the cotton mops. An ordinary wooden toothpick is dipped in liquid glue, and is then wound with surgical cotton in the ordinary manner. A large number of these cotton-tipped probes are prepared, and sterilized in the Arnold sterilizer for half an hour. After this they are wrapped up in a piece of sterilized gauze until they are required for use.

As to the knife best adapted to this operation. The old form of myringotome is practically worthless. The name myringotome is well chosen to designate the instrument. It simply makes a puncture in the membrane instead of a free incision. It is utterly impossible to secure a sharp cutting edge in a small instrument of this shape, and in many cases the point of the knife is so dull that it can only be forced through the drum membrane with difficulty. This not only increases the pain of the procedure, but renders it imperfect. I invariably use a small knife resembling, in shape, a sharp tenotome, the blade being about three-quarters of an inch in length. I always insist that these instruments shall be brought to so keen an edge that they will pass through a test drum merely by their own weight. Where the incision is to be carried outward along the superior wall of the canal, as in cases of suppuration in the tympanic vault, a rather stronger knife should be used. Here it is also more convenient to have the blade curved like the ordinary curved sharp bistoury, the length of the blade being about the same as in the instrument already described. Proper attention to the instruments renders incision of the drum membrane much less painful than it has usually been considered. In the majority of patients, general anesthesia is unnecessary.

Regarding the after-treatment of these cases, I still favor the old plan of frequent syringing. Drainage by a strip of aseptic gauze, is the ideal procedure. When the discharge is very profuse, the dressing needs to be renewed every few hours, and this is naturally, impracticable, both in hospital and private practice. I have used both methods, and find that better results are obtained if the canal is kept free from secretion by a frequent use of the syringe. The fluid employed should be either sterilized water or a weak antiseptic solution; such as a solution of bichlorid of mercury (1:5000). The medical attendant should give special instructions as to the manner of using the syringe, and see that these instructions are followed to the letter. The column of fluid introduced into the canal cleanses it from the discharge which has accumulated there, and, on account of its antiseptic properties, keeps the parts thoroughly aseptic until the ear is again cleansed. The frequency with which the syringe is to be used depends upon the amount of

procedure every two hours. In adults, once in three or four hours is usually sufficient. As the discharge diminishes, this interval is prolonged, and the irrigation is discontinued altogether when the discharge has ceased. It is stated by some that this plan of treatment is absolutely dangerous, and has occasionally been responsible for the unfavorable course pursued by the disease. The absurdity of such a statement is at once evident. If a patient is so ignorant that he can not carry out the syringing of the ear in the proper manner, much more mischief will follow the use of the gauze drain in the canal. I speak advisedly on this point, as my experience has been by no means small.

Very little need be said regarding the further treatment of these cases. An acute catarrhal otitis yields to treatment readily, unless the discharge is infected in the canal. In rare instances, it may be necessary to apply a solution of nitrate of silver, either to the external surface of the drum membrane, or even to the middle ear, before the vessels will regain their proper tone and allow the membrane to resume its normal condition. These cases are, however, exceptional. In acute suppurative cases, granulation tissue occasionally develops. Cauterization, either with a chromic acid bead or with a strong solution of silver nitrate, destroys this tissue completely, and restores the parts to their normal condition. When seen early, mastoid involvement seldom occurs.

17 W. 46th Street.

DISCUSSION.

Dr. RANDALL—It is but just that I should say a word as to the anatomy of the ear according to Leidy. Blake and others followed him by many years in adopting these divisions. Otologists do not realize as they should and must in surgical treatment, that the antrum is the posterior part of the tympanic cavity. The surgical treatment of the middle ear will have its proper basis only when these divisions are rightly realized.

Dr. Smith—Dr. Dench makes a distinction between catarrhal and other conditions. There may be a higher elevation of temperature and worse symptoms, but before we know what part of the tympanic cavity is inflamed, the point of incision seems to me not found.

INTRATYMPANIC SURGERY; ESPECIALLY IN CHRONIC PURULENT OTITIS MEDIA.

Presented in the Section on Laryngology and Otology at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY CHARLES HENRY BURNETT, A.M., M.D.

CLINICAL PROFESSOR OF OTOTOLOGY, WOMAN'S MEDICAL COLLEGE; AURAL SURGEON, PRESBYTERIAN HOSPITAL, ETC.
PHILADELPHIA, PA.

My experience in intratympanic surgery has been gained in 109 operations within the drum cavity, viz.: 43 operations for the relief of chronic catarrhal deafness and tinnitus, 26 for the relief of chronic tinnitus and tympanic vertigo (Ménière's symptoms) of catarrhal origin, and 30 for the relief of chronic purulency of the middle ear. In this article, however, I shall ask your attention to brief notes of the thirty purulent cases and the operations performed for the relief of this diseased condition of the ear. In all these cases various rational routine means had been employed for their amelioration before resorting to intratympanic operations. These operations have been performed upon the etherized patient, with one exception, Case 8, in which the dangling malleus was removed like a polypus with the polypus snare. The ear has been illuminated by means of a three-candle-

the ordinary forehead mirror, and supplied by a portable storage battery of six volts.

Case 1.—Miss M. of Philadelphia, age 23, a private patient. Attic suppuration and deafness in the right ear for six years. Sole perforation in the membrana flaccida. July, 1889, excision of membrana and malleus; malleus head necrosed; no trace of incus. Cessation of discharge, regeneration of membrana and great improvement in hearing the voice, from *nil* to fifteen feet, in the course of two months.

Case 2.—Miss F. D. of Philadelphia, age 48, a private patient. Chronic attic suppuration, left ear; sole perforation in the membrana flaccida. May, 1890, excision of remnant of membrana and malleus; no trace of incus; entire cessation of discharge in twelve days; improved hearing for the voice; chorda tympani irritation (metallic taste) on side of operation for six months.

Case 3.—Helen S. of Philadelphia, age 13, private patient. Chronic suppuration of the atrium of the right ear; sole perforation in the membrana tensa. June 11, 1890, membrana and malleus excised. Internal face of membrana covered with granulations; manubrium of malleus destroyed by necrosis; discharge diminished; hearing for voice improved from one foot to six feet.

Case 4.—Mr. W. H. N. of Philadelphia, age 30, private patient. Chronic suppuration of attic and atrium; perforations in the membrana flaccida and the membrana tensa. Suddenly an attack of pain and great vertigo; increased deafness. June 17, 1890, the remnant of the membrana and the partly necrosed malleus excised. Cessation of discharge in the course of a year. Deafness unchanged; no return of vertigo.

Case 5.—Mrs. Chas. G. of Idaho, age 32, private patient. Chronic suppuration of the atrium, right ear. July 7, 1891, membrana and malleus excised; malleus handle necrosed up to short process; discharge ceased in two months; hearing for the voice greatly improved.

Case 6.—Rev. I. McC. of Massachusetts, age 37, private patient. Chronic attic suppuration; sole perforation in the membrana flaccida. September, 1891, membrana and malleus excised; a little pus found in the atrium; hearing for voice slightly improved; nearly total cessation of discharge in the course of a year.

Case 7.—Edna P. of Pennsylvania, age 11, private patient. Chronic suppuration of the atrium. Oct. 7, 1891, excision of the membrana and malleus; malleus handle eroded by necrosis; diminution of discharge; hearing for voice improved; death from diphtheria a month after the operation on the ear.

Case 8.—Grace H. of Philadelphia, age 20, private patient. Chronic suppuration of attic, aditus and atrium; total destruction of membrana flaccida and membrana tensa, excepting anterior half of latter to which the malleus was attached. The latter was seized by a polypus snare and removed without pain to the unetherized patient. Total cessation of discharge in a few weeks, until March, 1897, when I removed a small cholesteatomatous mass from the attic and aditus. The discharge has now ceased. There has never been any regeneration of the membrana in this case; hence the easy and perfect drainage in recent cholesteatomatous suppuration.

Case 9.—Miss E. G. of Maryland, age 20, private patient. Chronic suppuration of the atrium, and secondarily, of the attic; sole perforation in the membrana tensa, in the upper posterior quadrant; complicated by ozena. Removal of the membrana and the malleus, March, 1892. Hearing for voice slightly improved; discharge diminished.

Case 10.—B. B. of Philadelphia, age 12, hospital patient. Chronic suppuration of the atrium; sole perforation in the lower part of the membrana tensa; excision of the remnant of the membrana and malleus; cessation of purulency in the course of a month; improvement in hearing for voice from two feet to twenty feet for isolated words.

Case 11.—Dr. W. H. of Iowa, age 32, private patient. Chronic suppuration of attic; sole perforation in the membrana flaccida; hearing for the voice very poor; membrana and malleus excised Aug. 10, 1892; body of the incus was found adherent to the head of the malleus; stapes plainly visible and movable with probe; improvement in hearing from one foot to 15 feet for a whisper and diminution of the discharge after the operation.

Case 12.—Henry T. of England, age 30, hospital patient. Chronic suppuration of the atrium; sole perforation in the membrana tensa; excision of the membrana and malleus August 3, 1892. Deafness unchanged.

Case 13.—Miss Edith H. of Pennsylvania, age 16, private patient. Chronic purulent otitis media in the left ear for five years; no tinnitus; voice heard four feet; scanty offensive discharge; large posterior perforation in the membrana flaccida;

malleus head and neck exposed; Nov. 30, 1892, I enlarged the perforation downward; atrium and attic found in free communication; cholesteatomatous mass as large as a pea removed from aditus after horseshoe incision about the manubrium; the latter was seized at the short process, with delicate foreign body forceps and removed alone as it was already detached by necrosis from the malleus neck; malleus neck and head found adherent to the inner surface of the scute of the squama; when removed with hook, the body of the incus was found adherent to malleus head by means of dense fibrous bands; hearing for the voice improved at once from four feet to ten feet; the discharge diminished in six months, but did not cease entirely; case withdrawn from treatment thereafter.

Case 14.—Harry P. of Philadelphia, age 9, private patient. Chronic purulent otitis media, right side, for several years; large posterior perforation in the membrana tympani with protruding polypi; Jan. 3, 1893, enlarged the perforation upward and backward; removed two polypi from region of aditus with an incus hook; after this clearance a central perforation was found in the membrana flaccida hitherto unseen and undiscoverable by a probe because of patient's great sensitiveness to touch in this region. Ligaments of malleus cut and bone removed; then the isolated long process of the incus was hooked out with the incus-hook; nearly the entire head of malleus had been destroyed by necrosis; its neck and short process were covered with fibrous bands.

This case has slowly grown better under the use of alcohol instillations and syringings. The only gain seems to be better drainage from the attic and antrum and within a year almost entire freedom from formation of polypi in the posterior part of the atrium.

Case 15.—Mrs. P. of Philadelphia, age 40, private patient. Chronic purulent otitis media in the left ear; neoplastic diaphragm with central perforation; no trace of malleus; excision of neoplastic membrana near annulus tympanicus; no trace of incus; stapes in position; cessation of discharge; improvement in hearing for the voice from one foot to six feet; regeneration of membrana without perforation in two months; remains well at present time.

Case 16.—Feb. 16, 1894; Charles M., age 15, private patient. Chronic purulent otorrhea, left ear, for many years; parents died of phthisis. Excision of thickened membrane and necrotic malleus; head of latter half destroyed; no incus found; attic filled with synechia and cholesteatomatous debris; lessening of discharge and improved condition of attic. Deafness unchanged.

Case 17.—March 7, 1894; Walter S., age 20, hospital patient. Copious chronic purulent discharge from the right attic and atrium; under ether removed two polypi and remnant of malleus; head of latter and part of the neck entirely eroded; nearly total cessation of discharge in a month; patient soon passed from observation.

Case 18.—March 16, 1894; Mrs. P. of New York, age 47, private patient. Chronic purulent discharge from left ear with large perforation in membrana flaccida; membrana tensa and manubrium intact and forming a pocket for pus; excision followed by entire cessation of inflammation and discharge in a year and a half. Deafness unchanged.

Case 19.—Oct. 15, 1894; Mrs. A. K., age 21, private patient. Chronic purulent otorrhea since childhood; attic and aditus involved; membrana destroyed; malleus and incus bound together by synechia; excised under ether; small cholesteatoma removed; hearing for the voice improved at once; total cessation of discharge in two months after operation; result has remained permanent.

Case 20.—Nov. 2, 1894; A. M., age 17, a negro, hospital patient. Chronic purulency of attic and atrium; hearing for voice two feet; large polypus removed from the right ear under ether; nearly total cessation of discharge in two months. Hearing unchanged.

Case 21.—Nov. 2, 1894; left ear of the above named patient. Similar lesions; hearing for voice two feet; in the same etherization removed remnant of malleus imbedded in polypoid membrana; nearly total cessation in two months. Hearing unchanged.

Case 22.—Nov. 12, 1894; P. N., age 13, hospital patient. Chronic otorrhea, right ear, for four years; mastoid operation by another surgeon several years previous to my first inspection of case; continuance of otorrhea; membrana largely perforated; hearing on contact; under ether, excision of diseased membrana and malleus; total and permanent cessation of discharge in two weeks after operation. Hearing unchanged.

Case 23.—March 6, 1895; boy 6 years old, hospital patient. Chronic otorrhea, right ear, for some years; excision of membrana and malleus; large perforation through upper posterior wall of auditory canal into antrum large cholesteatomatous

masses removed from attic and antrum; finally opened the mastoid cells to tip of process and removed foul debris from mastoid cavity, lying below line of perforation in canal wall into the antrum; entire recovery in a month; no record of hearing.

Case 24.—June 27, 1895; Mr. F. L., age 40, private patient. Chronic otorrhea, right ear, all his life; remnant of membrana retracted and malleus drawn up into empty attic; sole perforation in the membrana tensa; no incus visible; excision of membrana and malleus; latter eroded at tip of handle and rough over entire surface; total cessation of discharge in two months; hearing for the voice improved.

Case 25.—Feb. 29, 1896; Lizzie B., age 21, hospital patient. Chronic suppurative of the attic; complaints of tinnitus and vertigo; large perforation in the membrana flaccida; neck of malleus visible; membrana tensa drawn inward; excision of remnant of membrana and malleus; head of latter destroyed; no incus found; cessation of discharge in a month and relief of vertigo; hearing unchanged.

Case 26.—Oct. 20, 1896; Miss G. of Massachusetts, age 40, private patient. Chronic attic suppuration for years; excision of adherent and partly necrosed malleus; cessation of discharge and improvement in hearing for the voice from one foot to six feet.

Case 27.—Nov. 27, 1896; Master A., age 17, private patient. Chronic attic suppuration for several years; large perforation in membrana flaccida; excision of membrana tensa and the manubrium of the malleus, which had formed the outer wall of a pus pocket; cavity of tympanum filled with granulations; nearly total cessation of discharge in four months under alcohol and acetanilid; deafness unchanged as yet.

Case 28.—Dec. 10, 1896; Mrs. F., age 40, private patient. Chronic attic suppuration for years in the left ear; perforation in membrana flaccida both behind and in front of short process; membrana tensa and handle of malleus removed. Marked lessening of discharge; deafness unchanged.

Case 29.—Dec. 29, 1896; Mr. M. J. K., age 30, private patient. Chronic attic suppuration after typhoid fever six years previous. Excision of membrana tensa and handle of the hammer; atrium free from disease; copious discharge from region of attic and aditus; lessening of discharge up to present time; deafness unchanged as yet.

Case 30.—March 27, 1897; Louis L., age 16, private patient. Chronic attic suppuration for eight years; large perforation into attic and aditus; membrana tensa and handle of malleus intact; scanty, thick and offensive discharge from attic; excision of membrana and manubrium; head of hammer eroded; atrium free from disease; bichlorid syringing for four weeks and then an alcoholic solution of acetanilid to May 10, when discharge ceased.

Total cessation of discharge occurred in fifteen cases, marked diminution in seven, and diminution simply in eight. Total cessation of discharge occurred five times within two months, three times in one month; four times in two weeks, and once in a year and once in a year and a half. In the cases tabulated as "marked diminution" the favorable change took place promptly. The ultimate results in several cases are not known to me as they have passed from observation, while two are still under treatment as they have been recently operated upon and it is hoped they will be added soon to the list of totally cured. In those tabulated as simply "diminished discharge," two have recently been operated upon and are still under treatment.

The physical appearances in all cases have improved even when the discharge has not ceased. Granulations have ceased to form, and the discharge has become more mucous than purulent. The hearing improved in eighteen cases, was unchanged in eleven, in which the atrium was the principal seat of disease, and in one case, that of a child of 6, the hearing was unrecorded. The attic alone was affected in nine, the atrium alone in seven, and the attic and atrium together in fourteen cases. Marked ear vertigo was present in Cases 4, and 25; it was due in Case 4, in my opinion, to an irruption of the chronic purulency into the vestibule, through the foot-plate of the

stapes. This was demonstrated by the total deafness to all tests, in this ear after the cessation of inflammation and discharge. In Case 25, the ear vertigo was due to irritation about the stapes. In no instance has the stapes been resected or removed.

Alcohol instillations or alcoholic solutions of boric acid or acetanilid have proved most efficient in after treatment, as long as any signs of granulations were present. After these had ceased to form and the mucous membrane had become smooth, a solution of carbolic acid (2½ per cent.) or a solution of bichlorid (1-6000) acted best. In some instances when the discharge had become slight, simply mopping the fundus of the canal with absorbent cotton slightly singed seemed to perfect the cure. Case 14, has proved to be the most obstinate I have encountered; however, under the use of alcohol syringing at home, and alcohol moppings at my hand, granulations and small polypi have ceased to form in the attic and aditus. While preparing this article, Case 8 has had a recurrence of pain in her ear followed by the detachment of a lamellated mass of epithelium from the attic. The fundus is again entirely free from granulations and nearly dry under bichlorid mopping at my hand. When total cessation has occurred we may conclude that the disease was limited to the drum cavity and possibly the aditus. In those cases where the discharge has not materially lessened we may conclude that parts deeper in the mastoid have been and are still affected; perhaps less, however, than before drainage and antisepsis were improved by the operation. No case has been made worse by the operation, not even temporarily. Simply long continuance of the otorrhea in any of the cases noted above would justify a consideration of exposure of the middle ear cavities through the mastoid, as would also any appearance of so-called mastoid symptoms, which not one of them has shown since the operation on the drum cavity. The latter fact I think proves conclusively that so-called "excision" in chronic purulency of the ear by perfecting drainage from the attic and antrum, and facilitating antisepsis of these parts, tends to ward-off mastoid caries, sinus-phlebitis, cerebral abscess and pyemia, and should therefore precede any operation on or through the mastoid simply for the cure of chronic purulency of the middle ear spaces, especially in the absence of any urgent symptoms of mastoid necrosis and pain.

Certainly mastoid trepanation for the cure of chronic purulency of the middle ear will not succeed if the diseased tissues are not removed from the drum cavity at the same time, whereas purulency from the middle ear which has continued after a mastoid trepanation without excision of the diseased middle ear structures, will cease as soon as the latter operation is performed, as exemplified in case 22.

The hearing has been improved in fifteen cases, unaltered in ten, and in five instances it has been unrecorded. Among the cases of unaltered hearing are four recently operated upon; it is hoped they may be finally classed with those improved in hearing. Improvement in hearing has occurred seven times in which the attic alone was affected; six times in which the atrium alone was affected, and twice in instances of disease of both attic and atrium.

127 South 18th Street.

Let us defeat the Antivivisection Bill!

SOCIETY PROCEEDINGS.

The San Francisco Medico-Chirurgical Society.

Regular Meeting Feb. 7, 1898.

President, F. B. CARPENTER, M.D., in the chair.

After the transaction of routine business, Dr. CLINTON CUSHING read a paper on the subject of

CHOLELITHIASIS

entitled a "Report of Two Cases of Cholecystectomy," in which paper the technique of the work was the main feature.

Dr. L. C. LANE—I saw the operation in the first case. It was extremely difficult. The gall bladder was small and adherent to the liver. It tore somewhat in being severed from the attachment. The bleeding was hard to control also, but it was finally stopped by making a large black eschar with the thermal cautery. The man is now well. There was no rise of temperature after the operation. The diagnosis was in doubt—the case had the appearance seen in malignant disease; and the pain seemed characteristic of it. The physician who first saw the case, diagnosed cancer of the liver. My experience is that you know more about that, when you cut in and see. The pain is probably the most intense of any disease. The mucous membrane of the gall bladder is in folds, and is similar in arrangement to the Archimedean screw. This is claimed by some to be a means of facilitating the passage of bile.

Dr. J. O. HIRSCHFELDER—In the case described it would seem impossible to make a diagnosis; the atrophy of the gall bladder, and the absence of icterus lead to confused ideas, and the fallow look of the patient would also have a tendency to lead me astray. But the typical cases present no difficulty in diagnosis. Internal abdominal pains, mainly in the right hypogastrium, but not clearly localized. (A cause of pain in the right side may produce pain in the left.) The characteristic symptoms is icterus, coming on about or within twelve hours after the onset of pain. No other condition will produce icterus so rapidly, and the reason is that on account of obstruction, pressure in the gall bladder rises and forces a more rapid absorption of bile into the blood. Between the attacks, sometimes, by palpation the stone may, but not often, be felt. The stone may not be found in the stools until four or five days after the pain ceases. I direct that the contents of the chamber pot be mixed with water, then well stirred and thrown upon an ordinary flour sieve, and held under a running stream of water until all the material has been washed through, when the stones, if present, may be collected. If but one is found, and it is triangular in shape there are probably others not yet discharged from the intestine. In one week I have collected from a single patient fifty-six such stones.

The treatment need not necessarily be surgical. The object of treatment should be two fold: 1, increase the secretion of bile by administration of benzoates and salicylates; 2, induce contraction of the gall bladder if possible by administration of pilocarpin; by employing deep massage; by giving the faradic current with slow interruptions. I have seen results of value with the latter method.

Dr. G. R. HUBBELL—Some time ago a patient came to me, complaining of vomiting and pain in the abdomen immediately after eating. There were no other symptoms and the only sign was a tumor in the region of the pylorus. Examination of the stomach contents showed a full stomach seven hours after eating. The percentage of HCl was normal. Diagnosis was made of tumor of the pylorus. At the operation a stone was found in the common bile duct, but not closing it. The wall of the gall bladder was greatly hypertrophied and the stone had to be dissected out of the duct.

Dr. E. RIXFORD—In Dr. Hubbell's case, it was easy to pass a probe into the duct and reach the stone, but it could not be moved. By placing a finger in the foramen of Winslow and lifting up, the stone was dug out of the wall of the duct in which it was imbedded. The duct was closed with Lembert sutures. There was incessant hiccup for five or six days but otherwise no trouble during convalescence.

Dr. L. C. LANE—In 1854, when an interne, a woman came into my ward with a tumor of the liver. It was, in accordance with approved practice at that time, poulticed and finally opened, when a gall stone the size of a pigeon's egg was evacuated. After about three months the woman began to improve leaving behind her a legacy of gall stones amounting to nearly one hundred at the time she was discharged.

Dr. CUSHING—The study of this class of cases has proven to me three things of importance:

1. The pain is not so much in the region of the gall bladder, as in the abdomen generally.
2. The gall bladder is not necessary to the life of the indi-

vidual, although Bouchard says we secrete as much bile as urine.

3. When there is an inflamed and ulcerating gall bladder we may have a low continued fever lasting for months.

Dr. C. J. CROSS—Will the X-ray reveal the presence of gall stones?

Dr. RIXFORD—In Dr. Hubbell's case it did not. Gall stones are organic. In the radiograph the liver makes a deep shadow, the spine shows well above and below, but the site of the stones can not be distinguished from the liver shadow.

Dr. CARPENTER—I have tried to get a plate by having the rays obliquely arranged so as to have as little liver substance as possible intervening, but the results were failures to locate the stones although they were found present at the operations.

Gall stones placed on the outside of the body did not show any shadow.

EXCISION OF THE TONGUE AT THE THYROID.

Dr. E. RIXFORD presented a patient whose tongue had been removed at the hyoid bone for malignant disease. Kocher's method had been used. Its advantage is the wide field opened by the incisions. A preliminary tracheotomy had been performed, followed by the ligation of the lingual arteries on both sides. A very little sloughing had followed the operation.

PULMONARY TUBERCULOSIS.

Dr. RIXFORD—I also report a case of pulmonary tuberculosis cured with oxytuberculin. The lady is very enthusiastic over the remedy of Dr. Hirschfelder, but did not wish to come to the society. The patient is a lady about 30 years of age. Several members of the family have died from tuberculosis. In 1896 she nursed her sister who died from this disease. The girl was sick about three months only. It was one of the most rapid cases I have ever seen. Soon afterward this patient became ill and came to me in April, 1897. This note was made at the time: "Both apices slightly dull: bronchial breathing in both; coughing is constant; night sweats: exhausted; gradually losing weight; temperature 99 to 101; sputum large amount and swarming with bacilli. I prescribed creasote and whisky. At the time I wanted her to submit to Dr. Hirschfelder's remedy, but she declined. She went to Auburn, on the American River, and stayed a number of months, gradually gaining strength and health. In October last she returned to San Francisco.

Her coughing, however, was very severe; sputum contained pus, but although I examined it three times, found no bacilli. Night sweats were still present and she complained of great shortness of breath. Although she was considerably improved she began the treatment with oxytuberculin, beginning with injections of 3 centimeters and gradually increasing to 10; in all she has used 500 cubic centimeters. She soon began to improve; in two weeks she noticed that her cough was less; in December there was no sputum whatever. By January 1 she had no cough, no night sweats and could run up stairs and take long walks. Recently she walked ten miles. January 16 the injections were stopped and she was discharged as cured.

I think it right that all such cases treated by this remedy should be reported, those that improve and those that do not, in order that we may add to the clinical experience with this remedy. This was a case not very far advanced, but with tuberculosis in the family history the chances of recovery were against her. There has been no return of symptoms to this time.

Dr. G. R. HUBBELL—I wish to report four cases treated with oxytuberculin which are much improved.

Case 1.—Mrs. M. D., age 43, came to my office Nov. 13, 1897. No family history of phthisis. Patient caught cold in January, 1895; since then has been coughing and expectorating. From March until January, 1896, had night sweats—none since; she has had several small hemorrhages and is short of breath on the least exertion; vomits every morning. Weight in health is 135 pounds; at present, 112. On physical examination the right apex was flat to the fourth dorsal vertebra; in the left to the third; anteriorly, the right was flat to the second rib and the left to the third. There was amphoric respiration and bubbling rales of both apices. The sputum contained a large number of the bacilli of tuberculosis. Temperature was, A.M., 100; P.M., 103. Treatment with oxytuberculin was commenced at once in daily injections of 10 c.c. At the end of a week the temperature was, A.M., 99; P.M., 102. She was able to walk up two flights of stairs without stopping, which she could not do when she began treatment; her cough is better and expectoration less; she retained her food without any discomfort. She returned to her home and I heard nothing further of her.

Case 2.—Miss J. R., age 30, who came to me November 9, 1897, gave the following history: One maternal aunt died

of phthisis. One sister died of what was called consumption of the bowels. Patient had the usual diseases of childhood; was otherwise well until December, 1896, when she caught cold and began to cough; this has continued since and has been attended with profuse expectoration, blood-tinged at one time. In April patient had night sweats. At present she has dyspnea on exertion. Physical examination: Patient is poorly developed, illy nourished and pale; cervical glands slightly enlarged; thorax is moderately long, broad, moderately arched, deep; both supra- and infra-clavicular fossae are sunken; left side moves more than the right; flatness of the right apex posteriorly to the third dorsal vertebra; flatness of the left apex posteriorly to the second dorsal vertebra; flatness of the right apex anteriorly to the second rib; flatness of the left apex anteriorly to the second rib; amphoric respiration of the right apex with consonant râles; bronchial breathing at the left apex; râles in various parts of the right lung; otherwise the physical examination was negative. Sputum contained a large number of bacilli of tuberculosis. Temperature, A.M., 100; P.M., 102. Since November 9 she has had daily injections of 10 c.c. oxytuberculin. At present she is working nine hours a day; coughs and expectorates very little; has gained one pound in weight; her temperature is normal and she says that she feels well.

Case 3.—Miss H. L., age 20. I first saw the patient April 12, 1897. One sister died of phthisis. Patient was well until three months ago, when she caught cold and has been coughing and expectorating since. Her weight in health was 138 pounds; April 12 it was 127. Physical examination: Patient is well developed, well nourished but pale. Thorax well formed; left side moves slightly more than the right on deep respiration; there is dulness of the right apex to the second dorsal vertebra, posteriorly; anterior, to the clavicle; dulness of the uppermost portion of the left apex; bronchial inspiration and expiration at the left apex; sputum contains a large number of bacilli; temperature, A.M., 100; P.M., 102.4. For a month she received daily injections of 10 c.c. of oxytuberculin. At the end of that time her cough and expectoration had diminished; her night sweats ceased and she felt well enough to discontinue treatment.

Case 4.—Mrs. R. M., age 43. No heredity. Patient was well as a girl, but would always take cold easily. In June, 1892, she came to this city and took a room previously occupied for a number of years by a tubercular patient. The house was very dirty and required much cleaning and sweeping. Nov. 13, 1892, she gave birth to her first child; three weeks later night sweats commenced and about six weeks after that she began to cough and expectorate. She gained in weight subsequently, but cough continued off and on until three weeks ago, since which time it has been much worse and attended with profuse expectoration, pain in the right side and chest and dyspnea. Physical examination: Patient is moderately developed, well nourished, but slightly cyanotic. Cervical glands are slightly enlarged, thorax is moderately long, broad, moderately arched, deep; right side moves slightly less than the left; there is dulness of the right apex, posteriorly, to the second dorsal vertebra, of the left to the first; dulness of both, anteriorly, to the clavicle. Over the anterior part of the chest the percussion note is hyperresonant. The upper border of the liver dulness is at the seventh rib and the lower border of the lung moves but little on deep respiration; bronchial respiration of both apices with mucous râles; over other parts of the lungs the expiration is somewhat prolonged and over the right lung numerous râles are heard, with a faint friction sound over the lower lobe. The sputum contains a large number of bacilli: Temperature, A.M., 99; P.M., 100. For about three weeks she has had daily injections of 10 c.c. of oxytuberculin. In the beginning she raised sixteen ounces of sputum in twenty-four hours; at present she coughs a little in the morning and occasionally during the day and raises about one and a half ounces in twenty-four hours. She has gained six and one-half pounds in weight and is not short of breath on exertion; she ran four blocks without the slightest discomfort.

In passing, I will mention another patient who was far advanced in consumption, being confined to her bed and short of breath even when at rest. At the urgent solicitation of her friends and relatives and against my wishes I treated her. Improvement is marked, her color is much better and two days ago she was able to go down town.

All the cases here reported had been treated with the usual remedies for phthisis—creosote and cod liver oil without any benefit therefrom; these were not discontinued. With the exception of one case all were well advanced and yet all improved and two are well on the road to recovery. I have had the satisfaction of observing cases cured by the use of oxytuberculin and not only was the cure absolute, but none so far

have relapsed. In the so-called cures with creosote and various other remedies that I have examined, there remained some faint trace of the disease, but after cure with oxytuberculin all pathologic breath sounds disappear.

Dr. C. N. ELLENWOOD.—I will report a case that I have treated for eleven weeks: a girl 27 or 28 years of age who came to me Nov. 16, 1897, in the fourth stage according to Dr. Hirschfelder's classification (dyspneic at rest). She had hemorrhages with persistent coughing and profuse expectoration and this had existed for about two years. She had been a delicate girl through childhood; menstruation had been irregular and none at all for the past six or seven years; she was emaciated and weighed about 100 pounds. The left lung much flattened and contained a large cavity; vesicular murmur heard only at base; right lung dull at apex; vesicular murmur inaudible. The sputum was loaded with bacilli. I commenced with the daily injections of 1 c.c., increasing it gradually to 11. She has had these daily now for eleven weeks. In the beginning she had to be aided in ascending a flight of stairs, while now she walks up readily. She walks fifteen blocks easily. Her cough has disappeared for the most part, coughing only at intervals of four and five days. She has an expectoration of probably one-half ounce of sputum in the morning during the occurrence of coughing. The left lung is entirely flattened and there is an immense cavity. Her night sweats have disappeared for the most part; her complexion has wonderfully improved; this was observed after the first ten days; her appetite has also improved; she relishes her food and eats three or four times as much as before the treatment was commenced. There is marked improvement in the respiratory function. The right lung is the one she breathes with for the most part; very little action takes place in the left, yet respiration is becoming more and more prolonged. Her weight has fluctuated very materially, but still she weighs more than when she began; she is cheerful now, while before she was despondent. All in all she is very much improved by the oxytuberculin treatment. The bacilli have not disappeared, although they have diminished notably. I know of nothing else that would have given as great relief to this advanced case.

Dr. LANE.—In my cases and those which I have observed, I have seen no abscess or any considerable pain beyond the simple puncture of the skin by the needle; sometimes a slight pain is complained of, but by massage upon the point of injection that disappears. I have not seen the inconvenience from the puncture that some have complained of.

Dr. WILLIAM FITCH CHENEY.—I have treated several cases with oxytuberculin, and one of these in particular has given positive proof of improved condition. He was well advanced in tuberculosis, with the upper third of one lung gone, bacilli in the sputum, and the patient in a pitiable condition. He had had tuberculosis for two or three years and had been under treatment by some of our well known physicians by the usual methods, the last treatment being creosote in large doses. This man began treatment with oxytuberculin in doses of 3 c.c., gradually increasing to 20. At the expiration of a month he had less dyspnea. His expectorations were easier and he was generally improved. I was not much encouraged by the improvement; furthermore, I wanted to make a test of the treatment and find out what had helped him. I then gave him cod liver oil and a mixture of cod liver oil, and told him to go a week without oxytuberculin. During that week he was not doing as well as before; still I was not satisfied, and would not put him back upon the other treatment. In three days more he returned and said that he must have oxytuberculin or he thought he would die. He was becoming very despondent; was coughing almost constantly, and at his urgent request I returned to the original treatment. Within a week he was much better. He now sleeps all night and can walk about town without the exhaustion he formerly had. I can not think that man can be made well, but he has been made comfortable. He was treated ten days with other medicines and was anything but improved till oxytuberculin was resumed.

Dr. HIRSCHFELDER.—I have made distinct claims for oxytuberculin only in the first and second stages, before there is any shortness of breath on exertion; but, as these gentlemen have found, so I find in very advanced cases marked improvements occurring, and in some complete recovery from all symptoms, disappearance of the bacilli from the sputum and the return of the patient to perfect health. Where cavities are present they do not disappear but become smoother walled. In some cases the bacilli have disappeared from the sputum; the patient has lost the fever; strength has returned; there has been a gain in weight and results have been shown such as we might expect from iodid of potassium in syphilis. I might cite many confirmatory cases, but I will merely call attention to a striking

case illustrating what may be done in a field heretofore most disappointing:

J. A., aged 34, a tailor, was admitted to the City and County Hospital July 15, 1897, with the diagnosis of acute miliary tuberculosis. Dulness of the right apex to the second dorsal vertebra with bronchial respiration was found. The sputum contained large numbers of bacilli of tuberculosis. The urine, 32 ounces in quantity, with a specific gravity of 1016, was bloody and contained abundant tubercle in groups. The patient reported that he had been taken sick one week before and that he had been taken short of breath and weak. He was found to have general anasarca. His fever was high, ranging to 104 degrees. Injections of oxytuberculin were given and a rapid improvement in his condition took place. August 12 he reported that he felt better and thought he could breathe easier. His appearance was brighter. The edema soon disappeared. August 17 he got up and walked about the ward. The urine no longer contained blood nor bacilli, but the picric acid test showed a slight deposit. The fever had become lower, and September 10 the temperature became normal. Since November 14 there has been absolutely no elevation of temperature. The weight of the patient has risen from 133 pounds on August 28 to his present weight of 149 pounds. No bacilli of tuberculosis have been found in the sputum since December 30, and for two months past there has been absolutely no cough. Examination of the lungs fails to reveal the slightest sign of trouble. The urine is clear, although with Esbach's fluid a trace of albumin can be found. The patient's appearance is that of ruddy health, and he may be considered a case of cured miliary tuberculosis.

Denver and Arapahoe Medical Society.

Meeting of February 21, 1898.

THE DIAGNOSIS AND TREATMENT OF HEADACHES

was the subject for discussion. Dr. H. T. PERSHING divided the various kinds of headache into groups, taking into consideration the practical convenience in every-day diagnosis: 1. Headache due to organic disease—meningeal hemorrhage, optic neuritis, myelitis, encephalitis, abscess, tumor, chronic meningitis. 2. Headache due to diseased blood vessels, arteriosclerosis, syphilitic endocarditis. 3. Due to causes outside of brain, membranes or vessels, as migraine, infectious fever, diabetes, uremia, uric acid diathesis, alcoholism, indigestion, plumbism, active or passive hyperemia, anemia, eye-strain, nasal headache, dental headache, neurasthenia and hysteria.

In treating headache due to syphilitic infection, mercury and potassium iodid should be administered, even in cases where the infection is at all doubtful. Arteriosclerosis calls for glonoin in gradually increased doses to lower blood tension and for small doses of potassium iodid. Migraine is a very obstinate disease. Morbid conditions of the eye, nose, teeth, stomach or pelvic organs should be corrected, not with the view that they cause the disease, but because they irritate and exhaust the patient who is already sufficiently afflicted. The nerve treatment should be carried on during the intervals. Cannabis indica is more nearly a specific than any other drug. Beginning with one-twelfth of a grain of Herring's extract three times daily, the dose should be increased to the limits of easy toleration. The antipyretics may succeed for a few times but the dose must be rapidly increased and they soon fail to give substantial relief. The best treatment during an attack he considers to be codein and caffeine. In headache due to the uric acid diathesis, the diet should be regulated. Starch should be interdicted. He has seen many cases of habitual headache permanently cured by abstinence from all forms of mush and porridge. The salicylates are as truly specific as potassium iodid, for syphilis. No antipyretics should be given in cases of neurasthenia or hysteria. The persistent use will make the general condition worse. As a sedative opium and cannabis should be administered. Iron is of use, if the hemoglobin is reduced. Mineral acids seldom do good and often do harm. In cases of extreme weakness, the rest-cure as systematized by Weir Mitchell, is of the greatest value. There can, however, be no doubt that his success is due to his personal power of controlling and happily directing the mental state of his patients. A physician who does not possess these qualities will very likely fail with the rest cure. The mental treatment of such patients is an art full of difficulties. Complete reassurance after a thorough examination is the first and most important step in a well considered course of treatment. The patient must be taught to avoid talking of sickness, and to persevere in trying to crowd out the depressing thoughts.

Dr. McLAUTHLIN said that the majority of headaches are due

to derangements of the alimentary canal, the headache being frontal and interocular tension present. The treatment should be the old reliable calomel. He does not feel that we have in the salicylate a specific in cases of uric acid diathesis. We succeed very often only to upset the stomach of our patient. In the headache of typhoid fever, quinin and alcohol should be avoided as they only increase the trouble. In chronic heart disease, aortic or mitral insufficiency, nitroglycerin will be found of advantage.

Dr. LEVY spoke of the anatomy and physiology of the nose and the adjacent structures and showed how intrinsically they are connected, and therefore there is no wonder that in many cases the headache is traced to some derangement of the nasal passages or sinuses. He divided the pathologic causes into three groups, pressure, atrophy and diseases of the accessory sinuses. The atrophy which is an opposite condition to that of pressure, causes the headache by allowing the air to enter the lungs insufficiently warmed. The headache of the sphenoid sinus is quite distinct from those of the ethmoid and the antrum, the pain being localized at the center of the head and behind the eyes.

Dr. FOSTER discussed headache from the ophthalmologic standpoint. The weakened muscles without any organic trouble is a cause for headache. Hypermetropia, myopia, presbyopia and astigmatism were considered with reference to the one symptom of headache; glaucoma without special symptoms should not be overlooked.

Dr. AXTELL spoke of the headaches due to kidney diseases. He said they were uremic, and that but few escape headache some time in their course. In any cases of migraine occurring after middle life, granular kidney should be suspected. The cause of the headache is to be found in the retention of excrementitious matters, plus thickening of the dura and pia in contracted kidney. The treatment was elimination.

Dr. JAYNE took exception to the views of Dr. Pershing, who does not consider pelvic troubles causes of headache. He cited many cases which have been entirely cured from severe headaches by correcting the abnormalities in the pelvic region. He does not see any reason why the nose, the ear, the teeth should differ from pelvic organs in the causation of headache.

Dr. WARNER spoke from the stomatologist's standpoint, and dwelt upon diseased pulp as a cause of headache.

Dr. ROTHWELL added from the leaves of his experience the headaches due to concussion where no organic trouble is perceptible, and chronic ossific meningitis. He touched upon the question whether the pain is located in the brain or in the meninges.

Dr. HOPKINS considers that 90 per cent. of all cases are due to gastro intestinal derangement. In his experience he found headaches traceable to syphilis, which occurred early in the morning and were mistaken for gastric headache.

Dr. STROVER mentioned the headaches due to disease of the rectum. He advocated static electricity as a therapeutic measure in headache not due to organic lesions.

Dr. SPIVAK reported a case of headache which was apparently due to an elongated uvula, the amputation of which relieved the patient.

Dr. PERSHING, in closing the discussion, said that the difference of opinion between himself and Dr. Jayne lay in the pathology, but not in the treatment. Those who suffer from pelvic trouble are as a rule suffering at the same time from anemia and hysteria, and Dr. Jayne's cases can be explained on this ground. Besides, headaches are in a certain measure amenable to suggestive treatment. In many cases applications in the vagina or clipping the uvula are nothing else but suggestive treatment.

Drs. J. N. HALE and H. L. TAYLOR reported a case of partial dislocation of the occipitoatlantal articulation. A well-developed man, 26 years old, five feet ten inches high, weighing about 160 pounds, was lightly struck in the face and fell backward, striking his head upon the rail at the base of the bar at which he was drinking. He was dead before the arrival of the physicians. The postmortem showed, underneath the pia, much clotted blood. The brain was normal. The movement of the atlas by the finger inserted into the foramen magnum could be easily felt by the fingers applied posteriorly to the neck. There was no fracture. A ragged tear three-fourths of an inch long existed in the tissues binding the occipital bone to the atlas, and the right vertebral artery was entirely torn across just below the entrance to the cavity of the skull. Such cases are of extreme rarity, and only four cases are on record, those of Lassus, Palatta, Ballisson and Lariste.

Meeting of March 8, 1898.

THE RELATION OF WATER TO TYPHOID FEVER

was the subject at this meeting. The speaker of the evening,

Col. J. W. Hill, E.C., of Cincinnati, said in part: "The best informed sanitarians of Germany are firm believers in the water transmission of certain diseases, chief of which are typhoid fever and cholera, and visitors from the United States to that country who may be interested in the hygiene of water are reminded of the fact that in certain cities of Germany where the water supplies are known to be of very excellent qualities, typhoid fever is scarcely known. Dr. William Osler of the Johns Hopkins University, Baltimore, is authority for the statement that typhoid fever is so rare in Munich that enough cases can not be had to illustrate the disease in the hospital clinics. Unfortunately, no large city in the United States can boast of a lack of typhoid fever. Epidemics of typhoid have been traced to polluted water, but they are more often traced to some other dietetic substance, such as milk, oysters, water cress, etc., but in nearly every instance the source of the infection is something that has acquired its virulence from water or sewage. It is possible that the typhoid bacillus and other bacteria of sewage origin may survive for a length of time in a sewage polluted soil, but is antagonistic to our general knowledge of this and the bacilli of nitrification to suppose that two organisms of such opposite tendencies could survive in a soil where vegetation was in progress. A sodden sewage-polluted soil might be too rank for the nitrifying bacteria and at the same time furnish favorable ground for some of the bacteria of sewage origin, among which may be found *b. typhosus* and *b. coli communis*. A theory propounded, but unfortunately not expanded fully by Prof. E. Ray Lankester of Oxford University has suggested the probability that the typhoid bacillus has no independent existence outside of the animal body, and the colon bacillus upon the introduction into the human system becomes transformed into the conventional organism which we occasionally find in the spleen of a typhoid subject. In other words, the typhoid bacillus is an exacerbated form of *b. coli communis*. He points to the fact that the colon bacillus is of frequent occurrence in water used for domestic purposes, while the typhoid organism has been very rarely, if ever, found in water, and argues that a disease so prevalent as typhoid fever must have its cause in an organism better known than the typhoid germ of Eberth, and that that organism, in his opinion, is *bacillus coli communis*. The evidence to shake our belief in the water transmission of this disease is very meager, while upon the other hand, in cities like Munich, where a very excellent water supply has been substituted for a supply known to be polluted by sewage, the typhoid fever rates have quickly fallen to a small percentage of those which prevailed before. These reductions, simply by changes in the character of the water-supply to a city, have been so great as 85 to 90 per cent., and even if the remaining typhoid can not be charged to water, it is obvious that water is responsible for the larger percentage of the cases and death rates from this disease. The colon bacillus is always in the human intestine, and if it is the primary form of the typhoid germ, why is it necessary to look for its origin in water? The cities of Germany are extremely solicitous about their water-supplies and of a list of 121 but one, Riga, depends wholly, and one, Frankfort, partly upon unfiltered river water. Of a total population in these cities of 13,607,000, nearly 98 per cent. either obtain their public water supplies from unexceptional sources or rely upon slow sand filtration to properly purify such water, and it is not known that the sources of the other 2 per cent. of this large population are of questionable quality. Filtration among the Germans is not limited to turbid and polluted waters like those of the Elbe and the Maas, but is applied to comparatively pure water like that of Lake Zurich and to what we would regard as very pure water, like that of the wells sunk in the sand dunes at Amsterdam and The Hague. Some people take comfort in the fact that the typhoid bacillus is not a water bacillus and can not survive in water for an indefinite or even a great length of time. It can not certainly exist in water for more than a short period, but it is capable of doing great damage even during these brief intervals of time. We might contend that the cause of typhoid fever and other so-called water-borne diseases is not certainly known, but it would be unsafe to assume that water in some undefined manner is not concerned in spreading these diseases. The fact confronts us, that with a marked improvement in the quality of a public water-supply, there is a lowering of the typhoid fever rates, and so well grounded is the belief that water is the chief agent in transmitting the organism of this and several other diseases that most investigators have abandoned search for the cause and are directing their energies toward methods of prevention. Every year a withering blast sweeps over the land, and in its wake lie thousands of human victims and tens of thousands of shattered systems. The malignity of this stalking specter may be greater one year than another, but its purpose never changes; human

life is its constant prey and the flower of the land its choicest morsels. It is in our power to temper the blast and protect humanity from at least 85 per cent. of its ravages by remedies so simple that a child can understand them. Shall we do it?"

After the close of the lecture Colonel Hill illustrated by excellent stereopticon views three modes of water filtration: 1, The so-called continuous sand filter as exemplified in the filter beds of the London, Berlin and Hamburg water-works; 2, the intermittent sand filters as illustrated by the filter proposed by the Massachusetts Board of Health for the City of Lawrence; 3, the rapid mechanical sand filters used to a limited extent in this country, which requires a coagulant to make them effective in the removal of the finer suspended matter and bacteria in the water.

Col. A. A. Woodhull and Dr. Rogers followed briefly. The latter said that it was once an impression in Denver that the mountain streams contained the purest drinking water, but in many cases mountain fever, which is nothing else but typhoid fever, had been taken this way, and that twenty-five years ago when the population of Colorado was almost *nil*, and consequently could not have been ascribed to sewage pollution, the streams must have contained the germs of infection. Dr. Munn said that the success of the filter depended quite as much on the intelligence with which the filter was carried on as the method of its construction.

Maryland Public Health Association.

This meeting was held in Baltimore, Nov. 18 and 19, 1897. The sessions were held in the hall of the Medical and Chirurgical Faculty, and were presided over by Prof. Wm. H. Welch of Johns Hopkins College. The first paper was entitled

SANITARY ORDINANCES—POSTMORTEN,

by Dr. HOWARD BRATTON of Elkton. He said: Its application is hindered by: 1, legislation with penalties against uneducated half persuaded people; 2, difference of opinion among experts and disagreements of doctors in regard to more occult beget a disbelief and indifference to less hidden dangers; 3, acquaintance with best equipped appliances beyond their reach makes them loath to inaugurate any system at all. Attempts to do too much are unwise and result in nothing at all being done. 1. Burial in a cemetery should always require a permit. 2. No burial at all in this particular cemetery or the town limits. 3. Cremation the only proper means of disposal. It is the duty of the medical profession to instruct the public on matters of disease causation. By constantly hammering on the subject of infection with the object lesson before the class they can secure the adoption of prophylactic measures indoors and out, where carelessness and ignorance are the rule rather than the exception; by health associations, by united and individual effort and popular lectures; by systematic study of hygiene and sanitary science in educational institutions. This has at least the advantage of an early start. In fundamental principles of cleanliness, drainage, ventilation, house building, the more practical fields of fixed knowledge. At a later period the questions of unsightly structures, unhealthy surroundings and immorality may be studied in the light of nature. Professors of esthetics may determine how far esthetic defects are interdependent. An unhealthy town is not necessarily immoral. Next is the need and importance of vital statistics, for foundation for health department; to attract and hold the attention of the people. Theoretic knowledge should be evidenced by practical and beneficial results; hence these must be placed before the public.

Dr. PURNELL F. SAPPINGTON of Govanstown made a report upon recent experiences with typhoid fever in Baltimore County. He alluded to soil, air and water pollution, the spread of the disease by neglect of preventive measures and improper treatment of excreta. He considers the disease chiefly caused by impure water, and treated best by cold water and care as to diet.

A member having alluded to the contamination of the drinking water by the pouring into a cesspool of a quantity of coal-oil, as having for a time compelled people to discontinue the use of the wells, but that as soon as the oil had disappeared so the water could be used, they returned to them as a supply for their houses, Mr. Chas. Hartshorne suggested the pouring into the cesspools of a quantity of permanganate of potassa, which, by producing in the infected wells the appearance of bloody water, would at once make them a source to be avoided.

The next paper was

ON POLLUTION OF SOIL AND WATER,

by Dr. J. S. FULTON, secretary of the Maryland State Board of Health. Some years ago in England a man buried a barrel

of petroleum in his orchard. A series of wells averaging sixty feet in depth, and some as far as 900 feet away, were so affected by the diffusion of the coal-oil that even the cattle would not drink the water. In some parts of Maryland 90 per cent. of the private wells are found chemically unfit for use. In other parts a less proportion, but nowhere are so many as half the wells free from organic pollution. If the misuse which man makes of what he calls his land were permitted to work out its logical conclusions, the race would be extinguished. Man stupidly pours into his land as many as he has of the ingredients of a fatal prescription. Luckily, he is apt to lack the one thing necessary to complete the poison. When he possesses the deadly germ he flings it with the rest into the ground and feels no concern as to results. The consequences are more merciful than his conduct. He scatters, like a prodigal, the seeds of death, but kind mother Nature refuses the crop. He befouls the earth wherever he goes, but the sunlight, air, rain and countless hosts of living things are constantly busy cleaning up after him. It is only when he supplies more and worse dirt than these combined agencies can remove that outraged nature exacts the extreme penalty. The amount of scavenging accomplished by these silent, ceaseless forces is incalculable. Chemic examinations of the soil around and beneath old vaults show, in some instances, that within a surprisingly short distance the soil is pure. Widal and others poured quantities of pathogenic germs upon the earth at Granvilliers, and found that they rapidly perished. The bacteria of the soil are as a rule confined to a zone of from a meter to a meter and a half deep. The organisms of the upper earth are mortal enemies of the disease bacteria. Few disease germs have a good chance to survive in the soil under the changed conditions and in competition with the hardier organisms at home there. Direct sunlight is fatal to many species of bacteria. Drying kills many germs, while others are borne to destruction as dust in the air currents. Only a few harmful organisms, mainly those bearing spores, are able to withstand sunshine and dessication. The breeze which disperses a myriad of dried and inert plants may drop a few into soil fitted for their renewed activity. The sun, whose rays shriveled millions, warms hundreds into growth and releases other hundreds from the clutch of frost. The rain which buries some in the inhospitable depths of earth or sea, gives living drink to a parched few, and trickles into your well, supplying at the same time nitrogen upon which they feed. A vertical drain draws from an area having somewhat the shape of an inverted cone. How long its radius at the base may be is indicated by the coal-oil incident. Experiments have been made to determine the deeper radii, and it has been found that the angle of the drainage cone varies with the character of the soil and the rate of pumping. In fine sand, to pump out a foot of water depresses another well in the same stratum at a distance of twenty feet. In fine gravel, to pump out one foot affects a well twenty-two feet away. In chalk, one foot of depression is felt at fifty-seven feet; in sandstone at 143 feet, and in coarse gravel at 160 feet. If water levels are disturbed at such great distances, then the drainage area must be wider at the surface than the coal-oil incident would indicate. That observation shows that upon such soil nine wells would drain a mile. A Baltimore brewer, who tired of buying water at meter rates, sank an artesian well, securing a fine flow. Another brewer, inspired by his neighbor's success, drove a pipe to the same depth and the first brewer's water disappeared, never to return. These observations all show that among a series of wells there are oscillations of current in the common water supply, the direction of the stream being deflected toward one well or another as each in turn is used. If A uses 200 gallons in the morning, he gets part of the water of B's well one hundred feet away. In the afternoon B pumps 200 gallons, A's well being drawn upon for part of that amount. As the well is filled by the draining from every direction, so from the points of deposit, human waste is dispersed in every direction. It is customary to set apart two or three spots for the collection of these matters, but it is questionable whether in many instances the soil is not more widely polluted than it would be by indiscriminate distribution. Where deposit on the surface is practiced, ordinary care being used to prevent undue accumulation, the area of impure soil is usually neither wide nor deep. Under favorable conditions the bacteria in the surface soil do all the necessary purifying. Sometimes even under unfavorable circumstances, as under and around long-used vaults, the pollution of the soil has been found to extend not further than six or seven feet. This must not be taken as a general rule, however, for there is a saturation point for all soils, and as the bacteria, like other plants, have their seasons, the saturation point is variable. The barriers may easily be passed, and when this occurs, soluble impurities will sink through the soil in ever widening circles. The area of pollution

has a conical shape, base down. The width of the angle of pollution will depend upon the nature of the soil and upon its humidity. A wet soil diffuses chemic impurities widely. In a dry soil they sink more deeply. Impervious strata may conduct foul matter for long distances laterally. It is thus made plain that the attraction between accumulations of filth near the surface and the water in deep wells is mutual. The well exerts a steady pull, and the surface filth a steady push. Up to a high dilution, water increases the danger of soil contamination. For that reason, most pits are worse than surface closets. Shallow pits are good putrefaction vats, and in this process most of the contents become soluble. Cemented pits, if frequently cleaned are, so long as they remain water-tight, not offensive. But cement is soluble in sewage and the efficiency fails in a year or two. To remain water-tight, pits should be surrounded by at least a foot of well puddled clay. The grease from kitchen waste will preserve cement and keep a pit water-tight indefinitely. To the average suburban builder that is the chief reason for not admitting kitchen waste to the pit. Where water-closets are used, tight pits fill up very rapidly, and where sewer connections are impossible the expense of cleaning is a burden. This has led to the reprehensible practice of constructing cesspits of rough stone loosely laid in porous soil. Such rarely or never fill up and are said to be self-cleansing. They distribute vast volumes of foul water into the surrounding soil to be cared for by such agencies as chance or nature may provide, but so far from being self-cleansing, they are all befouling contrivances. Fifteen gallons or so of water with every discharge of the flush tank disperses filth much more widely through the soil than does the slow filtration of an ordinary vault or surface closet. When the service pipes of a water company are introduced into a house, the forsaken well is converted to a new purpose. The waste-pipes from closet and bath room are turned into it and it becomes the cesspit. It is a most economic procedure. The well is dug to running water and the local well digger will tell you that all the wells in the neighborhood have a very perceptible current from northwest to southeast. Thus without scruple the subterranean stream, which is for many people the only water supply, is befouled.

Prof. A. C. ABBOTT of Philadelphia gave a very interesting lecture upon

DISINFECTION.

He mentioned the use of sulphur, its value when burning in the presence of water so as to be thoroughly oxygenized. To be effective, the agent, no matter what it is, must be brought into contact with the article to be disinfected. Carbolic acid spray he considered valuable though not effective. The cheapest is ordinary white wash. It is not poisonous, nor injurious to furniture or clothing. Corrosive sublimate is undoubtedly effective, but highly dangerous. Heat is a valuable disinfectant in all cases. The utmost precaution is needed to prevent the spread of disease germs from the sick room, generally by carelessness of the attendants. In all cases of infectious disease the patient should be isolated so thoroughly that no article from the sickroom can carry out the germs. Clothing should be soaked in carbolic acid solution before being sent to the laundry. When the patient is well, before being removed his body should be well cleansed and clothed in fresh clothing, before leaving the room. If he dies, then the body should be made completely free from the possibility of conveying the disease in its progress to the grave or other disposal, and in either case, the sick-room must be cleansed as to the furniture, hangings, etc., and disinfection practiced so as to make it impossible for another to contract the disease by using the room. Under all circumstances, such a room should not be used for at least twenty-four hours after the removal of the case.

Dr. W. ROYAL STOKES of Baltimore followed with a paper on

DISINFECTANTS.

He alluded to a few fundamental facts as to the objects which these agents are directed, then said: The outcome of our experiments has been the discovery of two important methods of destroying bacteria or, as it is technically called, disinfection. 1. By physical agents: 2. By chemic agents. Heat is perhaps the most efficient physical disinfectant, and when infected materials are of little value this actual destruction of, by burning, is the surest way. So radical a method has a limited scope, but we may in many instances apply heat and destroy the infection without injuring the infected material. Experiments have shown that disease germs are all destroyed by exposure to a temperature of 212 degrees or steam-heat for one hour.

In case apparatus specially designed for this purpose is not available, such materials can be rendered harmless by boiling for about one hour in ordinary boilers. Though such measures

are sufficient for the ordinary household, it is often necessary in large hospitals, or at quarantine stations, to sterilize a great quantity of bulky goods at one time. Mattresses, pillows, clothing, blankets are placed in a steam-chamber and exposed to steam-heat until disinfected. Sunlight is Nature's disinfectant, and experiments have shown that direct exposure to its rays for a few hours will destroy such germs as tuberculosis, typhoid fever and diphtheria. The old method of exposing infected linen, carpets, etc., to the sun has thus been proven of value, and the rays of the sun must often destroy many of the bacteria present in infected hospital wards. This influence also is beneficial in destroying many of the bacteria deposited upon the surface of the earth, and even the upper layers of rivers must be somewhat purified by this agent.

The expectoration of consumptives should be deposited in a covered cup containing 5 per cent. solution carbolic acid, which soon kills the bacillus. The sputum can also be discharged into pasteboard boxes made for the purpose and cheap enough to be burned. Towels, handkerchiefs and all soiled linen from consumptives should be boiled or soaked in carbolic acid for twelve hours before being used again. The room should be dusted with cloth dampened with a weak carbolic acid solution in order to prevent the dust from rising, as well as to destroy the germs. Carpets should be swept with a damp cloth broom. For such diseases as typhoid fever, Asiatic cholera, where the intestinal discharges contain the infective germs, the stools should be immediately disinfected by pouring upon them an equal quantity of a 5 per cent. solution of carbolic acid, which should remain in mixture with the infectious material for an hour, before the vessel is emptied. The hands of nurses should be carefully disinfected after attendance upon the sick. Soiled linen should also be sterilized or burned. In diphtheria the discharges from the nose and throat are the chief vehicles of infection, and these can be received upon old linen cloths which are at once burned. If there is much expectoration it should be received in vessels containing carbolic acid solution. Bed clothing or linen which has been soiled by these secretions should be boiled, or disinfected by means of the last named solution. All articles which come in contact with the patient's mouth should be used exclusively by the patient and then carefully sterilized by boiling in a solution of common soda.

In such diseases as measles, scarlet fever, and smallpox, the same general precautions against the spread of the disease should be observed. All receptacles for intestinal discharges or urine should be cleaned by frequent flushings of water, and also occasionally disinfected with chlorid of lime. This is also an excellent material for the purification of the privy vaults or wells. It should also be used in large quantities upon garbage deposits or other collections of decomposing material. Streets and gutters should be frequently flushed with chlorid of lime. Formaldehyde gas destroys the germs of all these diseases. The gas is not poisonous, though extremely irritating to the mucous membrane of the eyes or respiratory tract. This may be avoided by rapidly opening the windows without drawing a full breath in the room, and by wearing closely fitting goggles.

(To be continued.)

SELECTIONS.

Soil Conditions and their Practical Relations to Tuberculosis and Other Infectious Diseases.—Dr. W. H. Welch, in the *Baltimore Health Magazine* (January) discusses the fate of pathogenic organisms which find their way into the soil. Although the nature of the relationship between the conditions of the ground and the prevalence of tuberculosis is not well understood, practical experience has shown that many localities have secured by good drainage of the soil, great reduction in the mortality from this most deadly scourge of the human race, a reduction amounting in some places to nearly 50 per cent. of the former death rate. Similar measures in Berlin and elsewhere have notably lowered the mortality among infants, particularly from summer diarrhea. Having once reached the soil, disease-producing germs may be conveyed to us in manifold ways. An important medium of transportation of bacteria from an infected soil is the water which we drink or use for domestic purposes. Among the various other ways by which harmful bacteria may reach us from contaminated ground it will suffice to specify their conveyance attached to particles of dust in the air, their transportation by flies and other insects,

and by domestic animals, their presence upon vegetables, especially those eaten uncooked, and our own direct contact with the soil. It is evident that the possibilities of infection from soil contaminated with disease germs are numerous and often intricate. The list of diseases whose causation has been shown to stand under certain conditions in more or less direct relation to contamination of the ground with their specific germs is a long one. Among the more important may be mentioned malaria, typhoid fever, cholera, yellow fever, dysentery, tuberculosis and the summer diarrheas of infants. Experience teaches, unmistakably, that contamination with the soil with organic refuse favors the development and spread of such diseases as these, and that drainage and purification of the soil by proper systems of sewerage are among the most effective measures for their prevention. No more instructive illustration of the value of modern methods of public sanitation can be found than the inability of Asiatic cholera to secure a foothold during the last two European epidemics, in clean cities, with proper sewerage and water-supply, and its ravages in notoriously filthy or insanitary cities, such as Toulon, Marseilles, Naples and formerly Hamburg. Authorities have differed as to the relative value of sewerage and of water-supply in influencing the prevalence of typhoid fever. We need not pause here to discuss this matter. Both factors are important, the drinking water usually the more important. But it is sufficient for our purpose to show that purification of the ground by proper disposal of sewage is one of the factors in determining a reduction in the occurrence of typhoid fever and other diseases. It is by no means an easy matter in all cases to assign to each one of the various recognized elements which go to make up an entire system of satisfactory municipal sanitation its due share in the beneficial result, for it rarely happens that one is introduced by itself alone, and the harmonious working of the whole system is often necessary to secure the best results from the individual factors, such as pure water-supply, efficient sewerage, good drainage, cleanliness of streets, improvement or removal of insanitary quarters, thorough sanitary inspection of dairies and food stuffs, public disinfecting establishments, hospital for infectious diseases, municipal laboratories, etc. In some instances, however, the conditions have been such as to furnish conclusive demonstration of the separate influence of the introduction of effective sewerage upon the death rate from typhoid fever.

A Modern Paladin and a Victor.—The *Sculpel* for November has a portrait of Mr. Victor Horsley of London, who was recently elected to the General Medical Council of his country. With it is a brief account of his professional qualifications and some facts relating to the vote that was cast at the election that made him one of the "direct" representatives of his fellows. The voting is done by mail. The number of ballots, or voting papers, sent out was 22,576. The voters returned 13,500, or 60 per cent. of these ballots within the proper time; 1050 ballots were too late or miscarried; 130 were defective; while 8061 or 35 per cent. were ignored. In other words, more than one-third of the electors appeared to be indifferent or not to take sufficient interest in the matter to cast its ballot. Mr. Horsley received 6946 votes; Sir Walter Foster 6112; the majority being 834. There were other candidates, but the balloting virtually concentrated on the two leaders. Mr. Horsley is classed as a London consultant surgeon rather than as a general practitioner, a fact that seems to be in the minds of some a root of bitterness; this possibly militated against a larger vote for him among the rural voters. Mr. Horsley's strong hold upon the profession appears to have come about in consequence of his arduous and efficient work in the Medical Defence Union. Mr. Horsley states that he will resign at the end of four years of his term, that being regularly for five years, in order to save the great expense that special elections involve, thus bringing

to one balloting all the general representative candidatures for the five year period next ensuing. One writer not overconfident in Mr. Horsley's soundness of judgment has said of him that he is one of the most brilliant men in the profession, with the great advantage of youth. He has so distinguished himself in science as to have been elected, in early life, a Fellow of the Royal Society, and in surgery as to be one of its most original and enlightened leaders. Nevertheless, he has always manifested the utmost sympathy with the general practitioner and he has displayed for years the most keen interest in defending medical men from all unfair conditions and unjust laws. He has, as President of the Medical Defence Union, acquired an almost unrivaled knowledge of the weak spots in the Medical Acts and the deepest sense of what is required for the honor of medical practice. He speaks with great clearness and force. He is, in short, a very strong personality. Has he no faults? He has the very faults of his virtues; he is impulsive. Sometimes he is prejudiced and occasionally rather too aggressive. He is apt to be borne along with the very impetuosity of his perceptions and convictions. He may not improperly be styled a modern medical Paladin, for like the champions of yore, he is ready whenever necessary to march into the enemy's country, and he has proved himself to be a hard hitter when the time for the encounter has arrived.

The Woerishofen Water Cure.—The death of Pfarrer Kneipp has not closed his establishment. Among those who will try to hold together his important *clientèle* are his pupils Dr. Baumgarten, Prior Reile and Dr. Mahr. A letter-writer from Woerishofen states there are over 2000 patients taking treatment at that place. Dr. Baumgarten is a Prussian from the Rhine district. He is quick, energetic, and has the perseverance of the Prussian. For six years he studied and practiced the cure under the eye of Father Kneipp. He is a firm believer in it. His knowledge of German, French and English, together with his knowledge of the cure, brings him a large number of patients. After the doctor comes the prior, or rector of the Brothers of St. John, who, thirty in number, have charge of the large *Kurhaus* in Woerishofen. Prior Reile is his name. Six or eight years ago Father Kneipp determined to perpetuate his cure in Woerishofen by means of some religious order which would reside and always remain in Woerishofen. The order of the Brothers of St. John, who have many hospitals in Europe, accepted the offer to continue the cure. Father Kneipp built a very large *Kurhaus*, gave it to the brothers, and the general of the society placed the brothers of the *Kurhaus* under the direction of one of them, who was called Prior Reile. The prior was given the duty to heal all people who applied to Father Kneipp by letter. The prior often received 200 letters a day. He gathered around him a corps of clerks to take charge of the large correspondence during the last six years, while Dr. Baumgarten has been practicing the cure in the village. The business of the prior became such that it was found to be necessary for him to have the aid of a physician to help him to correspond about the cases brought before him. Dr. Mahr, a Bavarian, was brought from Munich, who also learned the cure from Father Kneipp; so that today Woerishofen has three men who have studied the cure under its inventor, and have practiced it under his direction. At present each of them has his own *clientèle*, and their respective patients are more or less satisfied. Two thousand five hundred *kur-guests* are here from all countries, together with a sprinkling of the princelings and nobility of Europe, many of whom stand in need of the open air life and somewhat dogmatic handling and discipline to which they are pleased to subject themselves for a longer or shorter period. It may fairly be assumed that this "cure" will survive the loss of its founder about five years longer.

PRACTICAL NOTES.

Puncture of the Heart in Case of Air in the Veins.—Bégouin found that dogs and rabbits dying from asphyxia caused by

the introduction of air into the veins were relieved and saved by puncturing the right ventricle, in which he concludes that the air accumulates. He suggests that human lives might be saved also in this way under similar circumstances.—*Klin. Therap. Woch.*, January 30.

Bougination.—Dilating the Eustachian tube with a bougie introduced through a catheter, Grossard has found efficacious in curing tinnitus in 150 cases, applied three times a week for one to four weeks. It also improved the hearing in many.—*Presse Méd.*, January 26.

Carbolic Injections in Anthrax Infections.—A man with eczema of the ear became infected with virulent anthrax infection at the spot; fever, 104 degrees. In view of the threatening symptoms Natale treated the case with injections in the parenchyma of the part affected with a 2 per cent. aqueous solution of carbolic acid. The fever declined at once and in four weeks nothing was left but a small scar on the ear.—*Gaz. de Osp. e d. Clin.*, January 30.

Introduction of Mydriatics and Myotics into the Eye by Electricity.—In the cases in which the iris is rebellious to the action of atropin or eserine, if an electric current is passed through the eye, moistened with the solution, the effect of the drug becomes apparent at once. A current of two or three ampères will cause the absorption of a sufficient amount of a 1 to 300 solution to produce the desired result.—*Arch. d'Elec. Méd.*, June 25, 1897.

Disinfection of the Intestines.—In the disappointing search for a truly effective disinfectant, Lowenthal advises the investigation of the urine as a test for products of intestinal putrefaction. He has obtained with amiloform, which is decomposed in the intestines, developing formaldehyde, a marked diminution in the putrefactive processes in the intestines. It also acts as an intestinal astringent.—*Berlin. klin. Woch.*, 1897, 49.

The Arterial Pressure in the Early Diagnosis of Tuberculosis.—A comparative study of the records of cases of chloro-anemia and tuberculosis at the Paris Charité for many years, all showing subnormal arterial pressure, has impressed upon Papillon the fact which he announces as a suggestion to others, *i.e.*, that when the radical arterial pressure of a chloro-anemic patient is below 13 centimeters (Potain's sphygmomanometer), there is grave reason to suppose that she has incipient tuberculosis.—*Semaine Méd.*, January 22.

Iodoform in the Broncho-pneumonia of Measles.—Iodoform, 50 centigrams; cod-liver oil, 100 grams; spirit of anise, 2 grams. Commence with two teaspoons a day, increasing with the tolerance of the child. Combine with it inhalations of iodoformed turpentine. Gambardella reports that with this treatment the pulmonary symptoms and fever rapidly passed away, even when commenced tardily.—*Gaz. de Osp. e d. Clin.*, January 30.

The Constipating Effect of Atropin has been confirmed by G. Traversa by a series of experiments on horses and dogs. He therefore suggests that belladonna and its alkaloid are counter-indicated in constipation in man caused by atony of the intestines, but on the other hand they are logically indicated in saturnine colic in which the constipation is produced by spasmodic contractions of the intestines.—*Sem. Méd.*, January 22.

Intestinal Lavaguation in Infants.—Cordua reports twelve cases: two were cured by energetic massage, anemas and the insufflation of air. Five recovered out of seven operated on during the first two days; two died from shock. Three were operated after the second day, all dying from gangrene and consecutive peritonitis. From a review of 184 cases in literature, he concludes that in operating great care must be practiced to avoid hernia later. In a case of gangrene there should be resection, enterotomy, entero-anastomosis, but infants under a year can not stand such a serious operation and those over a year but little better.—*Gaz. de Osp. e d. Clin.*, January 27.

Double Hyposulphite of Sodium and Mercury in Syphilis.—A. Miceli states that he has been very successful with hypodermic injections of a solution containing 1 centigram of double hyposulphite of sodium and mercury to 1 c.c., the usual dose. This corresponds to 9 milligrams of metallic mercury, a larger amount than the 1 per cent. solutions of other hydrargyries. The injections were very slightly, if at all, painful and no secondary effects were observed in the fifteen cases treated, while the therapeutic effects were prompt and patients gained in weight.—*Semaine Méd.*, February 2.

Agar Jelly in Dermatology has been found extremely useful as it dries and can not be rubbed off, while easily removed with water. No bandage is required, and it is not necessary to heat the jelly. Another advantage over gelatin is its non-retractility. For erysipelas Gallois prepares a jelly with water 100 grams; gelose, 1 gram; corrosive sublimate and tartaric acid, à 10 centigrams. For external use. A thin layer is applied to the parts, renewed several times a day.—*Semaine Méd.*, February 2.

Quinin in Gonorrheal Arthritis.—Local applications are usually recommended, fomentations of turpentine possibly the most typical, but Maragliano administers quinin hypodermically and internally, as he considers it the best remedy against infections in general and also because the results of certain research seem to indicate that it has a specific action on the gonococcus. He rejects Bouchard's "pseudo-rheumatism" and Gerhardt's "rheumatoid arthritis," and endorses calling these arthritic affections by the name of the inducing affection.—*Gaz. de Osp. e d. Clin.*, February 6.

Glycosuria in Diabetics at Different Hours During the Day.—F. Schupper has been testing the glycosuria in the urine of diabetics at different hours and finds that the maximum is invariably between eight and ten in the morning, and the minimum during the evening and night. These results indicate that the patient can better support farinaceous substances inwards at night, and that test meals and examinations should be made early in the morning to determine the height of the pathologic process.—*Bul. d. Soc. Lancis. d. Osp. J.*, xxvii, 2.

Success of Injections of Calomel in Lupus.—Especially in old, tuberculous, ulcerating lupus, injections of five centigrams every tenth day produced remarkable cures, the improvement evident from the first. The lymphatic infiltration and exudation processes were arrested and retrogressed. Twenty-five cases are described in the *Ann. de Derm. et de Syph.* of January by Asselbergs, who considers calomel injections a most valuable adjuvant to the usual treatment. He observes that his success in the genuine non-syphilitic lupus deprives calomel injections of their hitherto assumed values as a diagnostic measure in syphilis.

Paraffined Gloves and Hands in Surgery. C. Menge not only uses the lisle thread gloves recommended by Mikulicz, but he renders them impermeable to liquids, while retaining their flexibility, by dipping them into alcohol after they are well dried in the oven, then into pure xylol and then into xylol containing ten grams of soft paraffin in solution to each 100 c.c. This solution is slightly warmed and the gloves remain in it fifteen minutes, when they are wrung out and dried again. They can afterwards be sterilized in steam. He also recommends rinsing the hands in the paraffined xylol after the usual alcohol sublimate toilet, wiping as usual. The hands shine then a little as if varnished, but they are no more slippery than usual, and there is no unpleasant sensation from it. He proceeds then directly to his operation, or puts on the paraffined gloves outside.—*Semaine Méd.*, February 2.

Faure's Method of Suturing Hernias Without Burled Stitches. J. L. Faure has improved on the Duplay and Cazin method described in the *JOURNAL* (Vol. xxvii, No. 26), by utilizing the

split hernial sac for threads to suture the inguinal ring. The sac is slit its entire length into two pieces, and these are tied in a double knot which closes the peritoneum. The two ends are then passed back and forth through the tissues, lacing up the canal, and tied in a double knot at the other end. This method can only be applied when the sac is of a certain size and firmness, but in these conditions it proves more than satisfactory.—*Presse Méd.*, January 2.

Antipyrin for Diagnosing Kidney Diseases.—Dr. L. Bremer, in a paper read before the St. Louis Medical Society, has expressed the belief that he has discovered a new method of diagnosing diabetic, pancreatic and kidney diseases by reason of the affinity of the blood and secretion of a diabetic patient for certain anilin dyes. His experiments demonstrated that the secretion of a healthy person has an absolute antipathy for the dye known as gentian violet. When the dye was poured into the secretion of a healthy person it remained floating upon the surface. When the same dye was poured into the diabetic urine it dissolved instantly and colored the whole fluid. The reaction of the dyes and acids upon the unhealthy secretions was most remarkable, showing the colors and sequence of the real spectrum, beginning with red at the base and ending with dark blue and white at the top. The blood of the subjects was affected in the same manner as the urine.—*Western Druggist*.

Flexion of the Spinal Cord Instead of Suspension in Tabes.—Eulenburg rather ridicules re-educating appliances, and advocates strongly the new substitute for suspension, stretching the spinal cord by bending the trunk forward at an acute angle with artificial, gradually increasing pressure (Gilles de la Tourrette and Chipault). The patient sits with outstretched legs on a long, low table. A couple of leather straps are fastened to the edge of the table and pass around the trunk in a figure of eight, crossing in front of the epigastrium and in the rear over the upper dorsal vertebrae. The ends hanging over the shoulders are fastened to a cross-bar, attached by a rope running over a drum, to a turning crank below. Pressure is regulated with a dynamometer. Applied for five minutes or longer, two or three times a week, he has not observed any inconveniences in his four months experience. It seems to be supported by the patients much better than suspension. The benefit was evident in the improvement in the ataxia and the disappearance of the lancinating pain, etc.—*Deu. Med. W'och.*, February 3.

Eucalin as a Local Anesthetic.—At the Montreal meeting of the British Medical Association, Drs. Horne and Yearsley gave the results of the use of eucalin as a local anesthetic in one hundred consecutive cases. The cases had to do with operations on the ear, nose and throat and are enumerated in the *Therapist* of January 15. They recommended 5 grain solids of eucalin hydrochlorid from which to prepare fresh solutions. For the examinations a 4 per cent. solution was used, and for the operations an 8 per cent. Upon the method of applying the drug depended largely the amount of anesthesia produced. It was found that in the case of the ear, a few drops instilled and kept in contact with the part to be operated on, by inclining the head, was more efficient than the use of saturated pledgets. The reverse was the case with the nose. The pulse was not materially affected in either rate or character, and in not a single case was there evidence that the cardiac action was influenced by the drug *per se*. It is true that eucalin induces hyperemia on application to the mucous membrane, but this rapidly passes off, and in no case was there excessive hemorrhage following operations under eucalin and not commonly met with in the use of cocaine. It was found that in the presence of acutely inflamed tissue, *e. g.*, acute tonsillitis, pharyngitis, etc., there was an increased flow of saliva, but in a non-inflamed tissue this effect was not produced. As to the disturbances of sensation, more particularly in the case of the pharynx, eucalin was less unpleasant and less marked than cocaine, but more transient, subjective sensations being normal in about an hour.

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, 100 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the *Editor*, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, MARCH 19, 1898.

LOCALIZED INFECTIOUS DISEASES AS A SEQUENCE
OF SLIGHT INJURIES.

Medical witnesses and attorneys are very frequently called upon to consider the claims of persons who having been more or less severely injured by an accident, attribute the subsequent state of their health entirely to this cause and bring suit against the railroad company, or the parties causing the injury, for damages. In a certain proportion of cases it is a well recognized fact that the claims of the plaintiff do not hold good. In some instances, for various legal reasons, he is non-suited and in others is defeated even if the case goes on trial. In still other instances, the trial having been completed, the jury awards damages which may or may not be in excess of the requirements of justice. With those instances where the patient's health and activities are permanently and directly impaired by an injury received from the carelessness of a common carrier, we shall not deal. Our interest, in this editorial, centers rather upon those cases in which no serious external manifestation of the injury exists, and yet immediately following the accident grave disease or perversion of function in some of the internal organs develops.

One manifestation of internal injury without marked external symptoms is so familiar to physicians and lawyers that it need not be considered, for the literature which has already accumulated in regard to it is both exhaustive and exhausting. There is a class of cases which is technically grouped together under the head of traumatic neuroses, a complexity of symptoms which in many cases renders the patient deserving of the amount which he sues for and in other

instances serve to defraud the defendant by reason of the fact that some of the symptoms of a traumatic neurosis can be fairly well aped by a malingerer. With those we shall not deal.

The question with which we especially wish to deal is indicated by the heading of this article, and our attention has been called to it in particular by a case recently on trial in one of the great cities of the Union, and by a very able paper by Dr. McDILL of Milwaukee, who writes in association with Mr. VAN ALSTINE of the Chicago, Milwaukee and St. Paul Railway (*The Railway Surgeon*, Jan. II, 1898).

In the case which we have referred to, a man, by occupation a grinder, and suffering from the early manifestations of "grinder's disease" of the lungs, was thrown with considerable violence from the platform of a street car and struck upon his right shoulder and chest with so much force as to seriously bruise the tissues about the shoulder and the tissues over the ribs in the axillary line. Within the course of a week or two it was noticed that the man's health had become very much impaired. Shortly afterward evidences of pulmonary disease became manifest and thirty-five days after the accident the man died. At the postmortem examination no evidence of external injury was manifest, the ecchymosis resulting from the accident having been absorbed. One lung was found almost entirely consolidated and the other partially so. Scattered through both lungs were a number of large deposits of fine metallic particles derived from the emery wheels and the steel which he had been accustomed to grind.

Suit was brought by the administratrix of his estate, it being claimed that his ill health and death within a short time after the accident was the result of the accident. It was admitted by the railroad company that the accident had occurred, and that so far as the accident itself was concerned, it was responsible. The question which rested upon the medical experts for decision, was whether the pulmonary disease which eventually resulted in the man's death could be attributed to the accident, and the testimony was such that immediately after it was heard the railroad company sought a settlement, which was granted. It was testified that severe injury to the chest might very readily so impair the vitality of the lung as to cause the rapid spread of disease already existing, but very mild in character, or to render the lung peculiarly susceptible to any infection to which it might be exposed. If the consolidation of the lung, which finally resulted in the man's death, was due to a tubercular process, then it would be very easy to understand how a violent injury to the chest wall might so disorganize the inflammatory exudations, which had been thrown out around tubercular and metallic deposits that they might be broken down, thereby making open the pathways for general infection. On

the other hand, it was possible that the micro-organism of pneumonia, always present in the upper respiratory passages of man, might find a ready soil for its propagation.

This testimony is of some importance in connection with cases of the character which we have mentioned and it is endorsed by a large amount of literature which has been accumulating during the last few years, particularly since accident insurance has become popular.

In McDILL and VAN ALSTINE'S paper they quote much of this literature which bears both directly and indirectly upon the case that has been cited. Thus SPENGLER, in the *Deutsche Zeitschrift für Chirurgie*, Part 2, p. 1, 1886, showed that in about one-half of 136 cases of joint tuberculosis, there was a history of antecedent trauma, and SABRAZES and BINAUD, in an article on "Tuberculosis of the Mammary Gland," assert that an accidental cause is necessary to start it. Then, too, JACCOUD, in the "Bulletin of the Academy of Paris," for 1896 has reported four cases of traumatic tuberculosis of the lung. In three of these the patients were healthy men before the accident and became tuberculous after suffering injuries to the chest. In two cases JACCOUD traced tuberculosis in traumatic pneumonia. Similar instances are quoted by McDILL from SCHILLING, WAGNER and others, and they themselves record a case of a young man of 26 years who after a severe injury died of catarrhal pneumonia, and a distinct line of injury could be traced from the skin through the pleura to the lung. SENN has also pointed out the close association between trauma as an etiologic factor and tubercular infection, and the fact that injury very gravely predisposes a part to infection by any micro-organism has been proved by a very large amount of experimental research. McDILL and VAN ALSTINE conclude, we think rightly, that clinical experience and experimental investigation show that infectious diseases often follow slight injury. They also believe that where negligence causes this injury and the injury proximately causes disease, both the injury and the disease are elements of damage in legal action. Two facts are to be carefully borne in mind in this connection, namely, that while on the one hand slight injuries may be followed by grave disease, on the other, patients learning of this fact may often seek to magnify the symptoms from which they are suffering, in order to obtain a verdict. It is necessary therefore for physicians and lawyers to remember that slight injuries may give rise to very proper suits for damage and careful notes of all such cases should, therefore, be kept, in order that a full history of the case from beginning to end may be at hand should suit be brought.

STATE AND COUNTY CARE OF THE INSANE.

The public care of the insane is now recognized in all civilized countries as an essential in some form or other, and the ideal system has been generally accepted as that in which the State at large assumes this duty. The State hospital or asylum of the present is an outgrowth of the humanitarian public spirit which revolted at the conditions under which the unfortunate lunatics formerly were kept in ill furnished and worse managed jails and poorhouses in which, in misery and filth, they dragged out an actively abbreviated existence. Undoubtedly the pendulum has swung to the other extreme in some instances; reformers are rarely conservative, and often are not broad-minded enough to see that by extravagance in their demands for a part they defeat their object as regards the whole; that a few of the insane are often thus housed in comparative luxury, while the great mass are in no wise improved in their surroundings or condition. The ambitions of architects and the satisfaction of local pride also have their part, and it may be political jobbery has also in some quarters had its share in favoring extravagance in asylum building with its consequence of enforced continuance of inadequate and irresponsible county care for a large portion of the insane. The result has been to some extent a reaction against the elaborate and expensive establishments of some years back, and attempts at less extravagant methods of caring for the insane. The necessity of State care has also been questioned, and in one State, Wisconsin, a plan has been devised and followed, which is claimed by its advocates to more completely meet the needs than any other as yet proposed. With the State hospitals for acute and violent patients they have in that State a system of county asylums, to which are sent the milder chronic cases that require less restraint, and are presumably hopeless as regards recovery, so that direct medical oversight and hospital care are not essential as far as they are concerned. The advantages claimed for this system of county care are, according to its advocates, who have brought over to their ideas certain philanthropists interested in this question outside of the State, first, its inexpensiveness as compared to the palatial State hospitals; second, a more normal mode of living for the insane, who are not usually accustomed to be housed "in palaces," more general employment of the inmates on the county farms, thus in a measure contributing to their own support; and third, that by it the State hospitals, relieved from the care of the chronic insane are the better able to devote their energies to the care of the acute and curable cases. They thus become more truly hospitals and not asylums or places for mere humane detention of a class that it is inconvenient or dangerous to permit to go at large.

There is no doubt but that these Wisconsin county asylums are a vast improvement over the average

county poorhouses, such as are still to be found in most of the States, and which still shelter a considerable proportion of the chronic insane. That the Wisconsin plan is the ideal system it is claimed to be, is, however, seriously to be questioned. The argument against it is very well stated by Dr. R. M. PHELPS in a recent number of the *Northwestern Lancet*, in which he shows that the claims of greater economy is to a certain extent fictitious when the total cost of the care for the insane in the State is taken into consideration; that the average per capita cost of the county asylums by their own figures is not less than that of some of the best State hospitals of recent construction, and notably more than some, that the home-like surroundings are likely to be in a measure also fictitious, unless we are to assume that all the chronic insane in these establishments are to be selected from the laboring class, a sort of social classification that one would think might be objected to by the taxpayers and inmates' friends. The strongest point made in their favor is, he thinks, that there is more employment given to the inmates than is the rule in the State hospitals; but this fact is not a necessary one, and there are large State institutions where the ratio is higher than in these county establishments. The argument he makes for the large State hospitals as regards medical care may be a little surprising to some who are now advocating smaller establishments with more purely hospital functions, but it will probably be found, as he says, that the best medical and clinical work today is being done in the larger institutions.

Against the county asylums Dr. PHELPS addresses the following arguments:

First, the lack of direct medical supervision. That this is of some importance can be shown by the fact that with the best selection of cases, the fact that they are all more or less defective degenerates and if they do not succumb earlier they are subject to the changes and diseases of senility, is sufficient to show the need of more than the interrupted medical oversight they receive. There is no possible comparison of the death rate of these inmates in the county asylums with what it would be were they under the closer medical oversight of the larger hospitals, but there is very little doubt that it would be unfavorable to them. Treatment for improvement of mental condition is by no means useless with the so-called chronic insane, and the more experienced the alienist the less inclined is he to be dogmatic as to the absolute incurability of this class.

Another important objection made by Dr. PHELPS is the tendency to reversion to poorhouse methods. The economy of rural county officials is well known, and, though he does not allude to it, it must be in some cases a factor operating against the proper meeting of the real needs of the insane. Another objection is the necessary lack of means of classification in these

smaller asylums and the consequent congregation of the disturbing and untidy with the others in these poorly equipped and attended establishments. The oversight of a board of control or of charities, who are fully committed to the advocacy of the system, is hardly as sufficient an assurance against all possible abuses as might be desired. It would be better to have this function deputed to its critics, or at least to those who from long experience with all the methods of caring for the insane in hospitals in the State and elsewhere, could intelligently judge the merits and deficiencies.

Dr. PHELPS's paper brings out strongly some of the leading drawbacks of the Wisconsin system, which is not, in any true sense, an ideal one, though where economic or other reasons prevent a better provision, it may serve a useful purpose. With thoroughly honest and economic methods in the State care of the insane, there is little to be said in its favor, even as regards expense, and that little is more than compensated for by the general results of enlightened medical care, which must necessarily be somewhat lacking in the county institutions.

THE GIANT CELL IN HEALING TUBERCULOSIS.

The morbid anatomy and histology of the essential lesion of tuberculosis have long been known, and while sixteen years have elapsed since KOCH's discovery of the specific parasite of tuberculosis, still, in the face of a vast amount of study, many questions relative to the source, the conduct and the fate of the elements of the tubercle remain unanswered. The giant cell of the tubercle—that prominent and well-known object—what is its origin and its destiny? The genesis of this element is still unknown; indeed, it is a point upon which such brilliant investigators as LANGHANS, BAUMGARTEN, WEIGERT, KOCH and METCHNIKOFF hold diverging opinions.

In the progressive and destructive form of tuberculosis the giant cell dies and becomes a part of the cheesy mass of necrotic material so evident in advanced tuberculous lesions. In case the destructive tendency of the infection becomes arrested from attenuation in virulence of the invading parasite, or from unusual resistance on the part of the tissues of the host, and a reparative process ensues, what then becomes of these monstrous multinucleated cells so abundantly present?

It is this question concerning the fate of the giant cells in healing tuberculosis that HEKTOEN (*The Journal of Experimental Medicine*, Vol. III, No. 1, 1898) has recently investigated. As material for his careful study the author was so fortunate as to obtain specimens from a case of spontaneously arrested tubercular leptomeningitis in an adult man; certainly a peculiarly suitable object for observation. The clinical conduct of the case was such as to lead

to a diagnosis of syphilitic brain disease, but the anatomic and histologic evidences pointed more strongly to a tubercular meningeal affection, and the question as to the nature of the infection seems to have been set at rest by the isolation and cultivation of the tubercle bacillus from the meningeal exudate, and by the discovery of a very few tubercle bacilli in stained sections of the pia-arachnoid. As to the reparative tendency of the process the writer presents six propositions, based on histologic evidences, to prove that the lesions are progressive and not regressive ones.

In this investigation HEKTOEN has centered his attention upon the giant cells in these apparently healing tubercles, and by a painstaking study of these elements in serial sections and in various situations, concludes that in healing tuberculosis the giant cell does not degenerate, is not absorbed or destroyed by phagocytes, but that its nuclei resume activity, as shown by their heightened affinity for nuclear dyes, and that the protoplasm becomes vacuolated and subdivided until, *from the giant cell, many small but perfect mononuclear cells arise*. From this it would appear that the giant cell, originating as a defensive histologic element to combat the invading tubercle bacillus (providing it does not succumb in the struggle), disposes of its ingested bacilli and, after a period of recuperation, subdivides into numerous small and apparently functional cells which seem to be identical with the formative endothelial cells of young connective tissue. HEKTOEN does not witness a complete reparative process in all giant cells, since in certain of these bodies necrotic processes like dispersion and solution of nuclear chromatin seem to occur in the same cell in which the new elements are forming.

If we are to believe in the indelible histogenetic impress which is assumed to be an attribute of the cell and its nucleus in regeneration of animal tissues, then these phenomena as interpreted by HEKTOEN would offer a strong argument for METCHNIKOFF'S view of the origin of tubercular giant cells from the fusion of mononuclear endothelial connective tissue cells, or from the multiple nuclear division of these cells. Its period of unusual exertion successfully ended, the giant cell returns to the elements which gave it birth—assuredly a very pretty example of that adaptation which nature so bountifully provides in the animal organism to meet the destructive agencies of disease!

EPIDEMIC CEREBROSPINAL MENINGITIS.

Recent medical journals contain articles embodying the results of the anatomic and bacteriologic studies of a recent epidemic of cerebrospinal meningitis in Boston, by COUNCILMAN¹ and his associates MALLORY and WRIGHT.

These reports furnish important additions to our

knowledge concerning this disease, as it occurs in America. This disease has appeared at various times in this country. Thus, it raged in Medfield, Mass., in 1806, extending over the New England States into Canada, Pennsylvania and Maryland, prevailing at some point or other until 1816. This epidemic corresponds to the first period of the history of this disease, according to HIRSCH.² The second period extends from 1837 to 1850, during which time the disease prevailed principally in France. The third period from 1855 to 1875, when the disease prevailed chiefly in Germany; but there were a number of local epidemics in America, one in Illinois, reported by JOHN B. HAMILTON, 1873 to 1874,³ and the fourth period, 1875 to the present time, during which time the disease has appeared in small epidemics in a great number of places. Thus, there was a considerable epidemic in Boston in 1874; in Lonaconing, Md., in 1892, and in New York in 1893. In this connection reference may be made to the report on epidemic meningitis published by ALFRED STILLE⁴, in Philadelphia in 1867, in which he describes the disease as he had occasion to observe it during an epidemic which ravaged the United States for ten or eleven years previously. STILLE saw 120 cases of the disease during the first quarter of 1867, in the Philadelphia Hospital. One hundred of these cases form the subject of a valuable report by Dr. GITHENS⁵.

It is interesting at the present time to read STILLE'S description of the anatomic characteristics, and of the causes of the disease, as they were taught at that time. STILLE summarizes the attempts of BAUDIN⁶ and others to prove the contagious nature of epidemic meningitis, by saying, that they fail most where most they need strength, namely, in the proof that the disease is ever communicated from man to man, and without that proof there is no evidence of contagion. One fact to which all American and European writers bear testimony, is the extreme rarity of its attacking physicians and nurses in attendance upon the sick, and those patients affected with other diseases who occupy adjoining beds in hospital wards. He says that we may know some external influences that appear to favor, but we know of none that are essential to, its generation.

During the winter and spring of 1897 there prevailed a small epidemic of the disease in Boston, and in the articles published by COUNCILMAN, MALLORY and WRIGHT, 111 clinical cases are considered. The largest number appeared in March, April and May. Here also there was found but very little evidence in favor of actual contagion. As a rule but single cases appeared in the same family and in the same house. A map of the city, giving the distribution of the sin-

gle cases, showed them to be well scattered. There is but little in the literature concerning the subject of immunity in this disease, and the problems of genesis and of the mode of infection are therefore still open for study.

The mortality of the 111 Boston cases was 68.5 per cent. The exact cause of cerebrospinal meningitis was first described by WEICHSELBAUM⁷ in 1887 as a diplococcus, which he calls the *diplococcus intracellularis meningitidis*, because in the lesions it is found almost solely within the cells. In the cultures this organism grows singly, in pairs and in fours. It is pathogenic to guinea pigs and rabbits, producing sero-fibrinous inflammations when injected into the serous cavities. Not much attention was paid to this demonstration by WEICHSELBAUM until 1895, when JÄGER⁸ found the same organism in twelve cases of epidemic cerebrospinal meningitis occurring in the garrison at Stuttgart. JÄGER's description corresponds very accurately with that of WEICHSELBAUM.

The most important result of the study of the Boston epidemic lies in the demonstration that in thirty-five of the cases in which postmortems were made, WEICHSELBAUM's diplococcus was found in thirty-one. Three of the four negative cases concerned very chronic instances of the disease. As a rule the organisms were easily cultivated in the acute cases, although it was soon found advisable to make a large number of inoculations, because the microbe evidently loses its vitality rapidly. The descriptions of the cultures and of the histologic lesions given by COUNCILMAN correspond in the main to those already published. Mixed infections with other organisms were not uncommon. The pneumococcus was found seven times; FRIEDLÄNDER's bacillus, the staphylococcus and streptococcus occasionally occurred.

In fifty-five cases lumbar puncture of the spinal canal was made during life, and in the fluid obtained diplococci were found in thirty-eight cases. The average duration of time from the onset of the disease to the date of spinal puncture was seven days in the positive cases, and seventeen days in the negative. On the whole, too much can not be said of the importance of lumbar puncture in making a diagnosis of the disease. There should always be made a microscopic and bacteriologic examination of the fluid, in order to ascertain exactly what organisms are present, because this knowledge is certainly useful in making the prognosis. Meningitis, apart from the epidemic form, is commonly caused by the tubercle bacillus, the pneumococcus and the streptococcus. Naturally these cases of meningitis are usually secondary to infection elsewhere. In a series of cases of this kind referred to by COUNCILMAN the pneumococcus was found ten times. COUNCILMAN and his collaborators express the important opinion that all the infections

of the meninges, other than with the diplococcus intracellularis, are fatal. The complete proof of this can not be determined except by microscopic and bacteriologic examination of the exudate during life by spinal puncture. If tubercle bacilli, pneumococci or streptococci could be found in a case of meningitis which recovers, it would settle the point. Clinical observation alone can not do it. As the cases of epidemic meningitis become chronic and tend toward recovery, the fluid withdrawn by puncture, hitherto purulent, becomes clear and the number of organisms present diminishes very rapidly, hence the prognostic significance of repeated puncture.

This is not the place to enter into a lengthy description of the histologic changes found. It is interesting to note the condition of the lung, however, on account of the relation which is very generally supposed to exist between epidemic meningitis and pneumonia. In thirteen cases there was congestion with more or less edema; in seven cases there was bronchopneumonia, most marked in the lower posterior part of the lung. In two cases there was a characteristic croupous pneumonia, and in the lung of these cases pneumococci were found. In eight cases lung changes due to the diplococcus intracellularis was found in the form of small bronchopneumonic foci. In one case the consolidation was so extensive that it might easily have been considered as a typical croupous pneumonia. The lung complications due to the pneumococcus may, according to the statistics of the Boston epidemic, take place in almost any period of epidemic meningitis. Thus, in one case pneumonia developed after the meningitis had existed for seventy-four days.

From these and other investigations it appears definitely settled that the disease known as epidemic cerebrospinal meningitis is caused solely by the *diplococcus intracellularis meningitidis* of WEICHSELBAUM, which must be looked upon as a distinct and separate species of micro-organism and not merely a variety of the pneumococcus. Furthermore, that great care must be exercised in attributing leptomeningitis when it occurs in connection with croupous pneumonia to an infection with the pneumococcus alone, because instances of mixed concurrent infection with these two forms of diplococci appear to be not so very infrequent. As already indicated, the manner of infection in epidemic meningitis, the distribution outside the body of the specific micro-organism, and other questions concerning the origin of the disease, merit further investigation.

CORRESPONDENCE.

"The Humane Society Deal in Fiction."

REPLY TO THE STATEMENTS MADE BY THE PRESIDENT OF THE WASHINGTON HUMANE SOCIETY IN A LETTER ADDRESSED BY HIM TO EACH SENATOR OF THE UNITED STATES.

BALTIMORE, MD., March 7, 1898.

To the Editor:—In your issue of March 5 (p. 565), you pub-

⁷ Quoted by Councilman *et al.*

⁸ Centralbl. f. Bact. u. Parasitenkunde, 1895.

lish under the caption "The Humane Society Deal in Fiction," a letter addressed by Mr. A. S. Pratt, the president of the Washington Humane Society, to a well-known Senator, urging him to vote for the antivivisection bill now before Congress. A letter with the same contents was sent to each Senator. In compliance with the request of one of the Senators that a reply be made to the statements of Mr. Pratt, I have sent this Senator a letter from which I beg to send you the following extract. Most of the points were covered more fully in my paper "Objections to the Antivivisection Bill," published in the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, Feb. 5, 1898, and published also as Senate Document 104, 55th Congress, second session. Mr. Pratt, I am informed, is engaged in the insurance business in Washington.

Very Respectfully, WILLIAM H. WELCH, M.D.

1. Senate bill 1063 is correctly described as an antivivisection bill, and the only reason which Mr. Pratt or any one else can have to assert the contrary is that it does not totally prohibit all experiments upon animals. It originated with the Washington Humane Society, a notoriously antivivisectionist organization, whose president (Mr. Pratt) says in his annual report for 1894 (p. 24): "The subject of vivisection has been frequently before your executive committee during the past year and but one sentiment has been expressed, viz., that of utter abhorrence and condemnation of the inhuman practice." The great majority of the advocates of the bill are antivivisectionists.

The great body of medical and scientific men of this country are practically unanimous in opposition to the bill, not a single medical or scientific society having expressed itself in favor of it, whereas considerably over a hundred such societies, including all of the important National and State and many local societies, have passed resolutions remonstrating vigorously against its passage.

The bill is an antivivisection bill not only because it originated with and is advocated by antivivisectionists, but also because it prohibits many important and useful kinds of experiments upon animals, surrounds the performance of others with such restrictions as virtually to prohibit them, and in fact permits no experiments whatever save under extremely vexatious conditions. The contention so much insisted upon by advocates of the bill that it is not prohibitive of any useful experiments can not be admitted for a moment by any one acquainted with the bill and familiar with the purposes and needs of experimental medical and biological science.

2. The summary of the provisions of the bill given by Mr. Pratt in the second paragraph of his letter is grossly incomplete and misleading. Among the objectionable provisions of the bill which he does not mention are:

a. No one, except an officer of the government of the United States or of the District of Columbia, can perform an experiment without first procuring a license from the Commissioners of the District, who can refuse all such applications if they choose to do so. It would be difficult to show what qualifications these Commissioners possess, or are likely to possess, to enable them to judge of the fitness of medical and scientific men to make experiments upon animals.

b. In addition to a license, a special certificate must be procured in case any one of certain commonly used animals is to be employed for experiment.

c. The Commissioners may call at any time upon experimenters (including officers of the United States Government) for reports upon the methods and results of their experiments, and the official inspectors are required to publish the results of their observations. Many important experiments would not be undertaken under any such vexatious conditions as these.

d. The Commissioners may require any place where experiments are performed to be registered. They may disallow or suspend any certificate without any hearing on the part of the holder. In a word, the Commissioners are made the dictators of the medical profession in matters requiring expert knowledge and sympathy with the needs of medicine.

e. With the exception of certain demonstrative experiments for lectures, the only experiments permitted by the bill are those intended for the advancement of knowledge by *new discovery* and this knowledge must be of one of two kinds, either physiological, or for saving or prolonging life or alleviating suffering. This excludes such experiments as those often practiced by the surgeon to acquire skill in operating and those for the confirmation of alleged discoveries by others.

f. The bill permits the use of only two anesthetics, ether and chloroform. There are other anesthetics, in some cases

essential for the purposes of the experiment, and it is absurd to prohibit their use.

g. With the exception of inoculation experiments, tests of drugs or medicines and tests of surgical procedure, no animal is permitted to survive after an experiment unless kept continuously under the influence of ether and chloroform. This provision prohibits a large number of important and useful experiments.

h. The bill prohibits the granting of a license to any one under 25 years of age, unless a graduate of medicine duly authorized to practice medicine in the District of Columbia. As Dr. Dabney has pointed out this excludes a large proportion of well trained biologists such as are employed in the Bureau of Animal Industry.

The foregoing are only some of the objectionable provisions of the bill which Mr. Pratt neglects to mention. This bill is in fact a very complicated measure, loosely drawn and doubtful in the interpretation of some of its provisions, and calculated to inflict most serious injury upon the progress of medicine and biology in this country. It is copied in large part from a British law, but goes further in its restrictions than the latter, which has proven to be most injurious to medical science in Great Britain. The whole impulse for this legislation started among antivivisectionists in England some twenty years ago, but thus far other countries, including our own, have been spared such an infliction.

3. Mr. Pratt is in error when he asserts that "ordinary inoculation experiments are expressly excluded from the operation of this law." The only concession regarding this class of experiments is that they may be made without the administration of anesthetics. All of the other vexatious provisions of the bill apply to inoculation as well as to other experiments.

4. Accusations of "revolting cruelty and barbarity" in the performance of scientific experiments upon animals, of which Mr. Pratt and the Humane Society profess to have "certain knowledge" are made in the most reckless and wanton manner by antivivisectionists. Mr. Pratt's statements with reference to alleged cruelty and secrecy in the performance of experiments in the District of Columbia and elsewhere in this country are unsupported by evidence. Not a single authenticated example of such cruelty, that is, the heedless infliction of pain, has he or any one else been able to adduce in the District of Columbia. The Superintendent of Public Schools of Washington, in a letter dated April 24, 1896, has officially stated that no vivisection experiments are performed in the public schools of that city, and that they never have been performed there. Those who have the best opportunities to know the real facts are confident that no cruelty exists in the performance of animal experimentation, which would justify any restrictive legislation whatever in this country. If any instances have occurred, they are certainly most exceptional, and are quite within the power of public opinion, including that of the medical profession, aided by the ordinary law, to cope with.

5. The charge of secrecy in the performance of animal experiments is without foundation. These experiments are published in scientific journals with full details, and any properly qualified person has free access to laboratories where such experiments are made. The scheme of inspection provided for in this bill may readily lead to a system of outrageous espionage utterly foreign to our system of government, and degrading and intolerable to the scientific men who conduct the experiments.

6. Mr. Pratt's utterly baseless and absurd, I do not hesitate to say wicked, charge that members of the medical profession are educated to "utter indifference to the infliction of pain and the sacredness of human life" and subject the sick poor in hospitals to experimentation, is an example of the recklessly false assertions of antivivisectionists. It is inconceivable that statements of this character, which fairly represent those upon which the antivivisection agitation is based, should be allowed to influence legislation in the Congress of the United States.

7. Mr. Pratt's argument that experimenters, because they do not concede any abuse of vivisection in this country justifying the proposed legislation, should be willing to submit to the provisions of such a bill as Senate bill 1063, seems to me too absurd to require comment.

8. Medical and scientific men very naturally and properly object to penal legislation directed exclusively against them in the conduct of investigations which they believe to be of the utmost importance to scientific and practical medicine and therefore to humanity. The District of Columbia already has an effective law for the prevention of cruelty to animals, which permits only properly conducted scientific experiments under proper authority. Those who conduct experiments are no less subject to this law than other members of the community. No special or class legislation on this subject is needed and such legislation is offensive in the extreme.

9. It is true, as Mr. Pratt states, that Senate bill 1063 was reported unanimously by the Committee on the District of Columbia. I believe that I am correct in stating that this matter was left by his colleagues on the Committee very largely in the hands of Senator Gallinger, who would seem from his report on the bill to be an extreme antivivisectionist. He must by this time realize that in this matter he has antagonized the sentiments of the great majority of medical and scientific men of this country. There never was an adequate presentation of the arguments against the bill before the Committee. I have information that at least some members of the Committee have changed their opinions and are now opposed to the bill.

10. It is likewise true that a very impressive list of names is attached to a petition favoring this legislation. Here again I know of some who, having become better informed, have written letters retracting their consent. You know better than I how much value is to be attached in general to such petitions, for which it is sufficiently easy to secure signatures. Undoubtedly not a few of the general public have been misled by the grossly false, misleading and sentimental appeals of antivivisectionists. Upon this matter it is the voice of science and of medicine, which is likewise the voice of true philanthropy, which should be heard and which should control legislative action, and not that of those who, however worthy their impulses, however high their social position, however great their knowledge in other departments, do not possess that special knowledge which renders them competent to judge of the merits of this question. The voice of science and of medicine, so far as it receives authoritative utterance, is overwhelmingly opposed to any such legislation as that contemplated by this bill.

As to the necessity and great value of animal experimentation to scientific and practical medicine, both human and veterinary, and to biological science, there is practically no difference of opinion among well informed medical and scientific men. Thousands of lives of both human beings and animals have been saved and in increasing number will lives continue to be saved by knowledge which could have been gained only through experiments on animals.

In conclusion permit me to express my gratification, and I may safely add the gratitude of all enlightened physicians and scientists, that your powerful influence is being exerted in opposition to the enactment of Senate bill 1063. In this you have espoused the cause not only of science but also of humanity.

Malaria Infection.

CHARLOTTE, N. C., March 7, 1898.

To the Editor:—In your remarks under the above heading, in the issue of March 5, 1898 (page 561), you make some statements which appear to deserve some qualification, at least from my information and experience on the subject. That there is a form of malaria (the disease) which resists the therapeutic action of quinin even when in proper dosage by the stomach, rectum and skin, is within the experience of a number of physicians throughout the South. This form of malaria, designated the estivo-autumnal, will not infrequently persist in spite of the exhibition of large and repeated doses of quinin, the patient dying literally saturated with the drug and thoroughly cinchonized. Dr. Osler, the highly gifted and capable authority quoted to support the points of the editorial, has given absolute testimony to the fact that quinin *will not* remove the crescentic forms from the blood and that the fever will persist in spite of its use. Writing to me in answer to a communication, he replies to the question as to whether in his experience there was a form of malarial fever that resisted quinin: "Yes, the estivo-autumnal resists in certain phases. The organism—crescents—do not disappear." I take this to mean that there is a form of malaria which will not yield to quinin no matter how employed. The action of quinin upon certain types of malaria is very positive and undisputed. There are, however, phases or stages of what was doubtless originally a purely malarial affection, yet the precise nature of the pathologic phenomena soon becomes obscure and we deal with agencies supplementary to those originally and still present.

Exactly what constitutes this addition to the crescents already present in the blood, we have no present adequate

answer. We know enough to know that the pathologic condition is not amenable to the therapeutics of quinin, no matter how much or by what avenue it reaches the blood.

Respectfully,

J. WELLINGTON BYERS, M.D.

Oxytuberculin.

SANTA CLARA, CAL., March 12, 1898.

To the Editor:—My attention has been drawn to a letter in the JOURNAL about oxytuberculin by Dr. E. H. Smith of Santa Clara, Cal. It is not my custom to reply to such letters, but a few facts will be at least interesting.

There are seven (or more) physicians in this county who have used oxytuberculin. How many of the cases treated by these physicians have been observed by Dr. Smith I am not able to state, nor do I know whether or not Dr. Hirschfelder has diagnosed all the cases of tuberculosis treated by these men. The letter states, "It is a very noticeable fact that all of the cases seem to be diagnosed by one individual, viz., Dr. Hirschfelder."

For myself I shall reply, and will be glad to hear from the others. Dr. Hirschfelder never examined a case for me (nor the sputum) for at least three months after I had used treatment; nor has he ever diagnosed a single case for me. I have several times submitted the samples of sputum to him for satisfaction and for preservation of a slide by him. One case of mine to which Dr. Smith refers as "observed" by him, the letter states "That was a case of 'asthma,' and no positive evidence of tuberculosis at all. This case has been reported cured."

Now this case has never been reported "cured."

Dr. Smith has never examined this patient, and yet he states "These cases are not presented to an unbiased medical profession for diagnosis." What could be more biased than to say that a certain case was "asthma" and not "tuberculosis," without having made any examination. Let us see whether or not this was a case of "asthma:" and, notice, that before oxytuberculin or Dr. Hirschfelder were known to me at all, this case was diagnosed "consumption" early in 1896. Dr. P. M. Lusson of San Jose, examined the patient and gave his diagnosis as "pulmonary tuberculosis in both lungs." I was not acquainted with the patient at that time. On Aug. 6, 1896, this patient presented herself at my office for examination. My notes taken at the time are as follows: Temperature 101.5 degrees; pulse 104; cough very annoying; losing flesh; expectoration abundant; left lung affected to third rib; right lung to fourth rib; nocturnal paroxysms of asthma causing patient to smoke asthma powder from six to fifteen times a night; weight about 103 pounds; usual weight for five years 110 pounds; microscope shows abundant tubercle bacilli. Diagnosis: Pulmonary tuberculosis, complicated. Treatment: Outdoor life, generous diet, tonics, creosote carb., protinuclein, etc., with cough mixtures.

November 6, gradual decline; weight about 100 pounds; no improvement.

November 16, tubercular pleurisy, severe; tubercular foci throughout both lungs.

Dr. I. N. Frasse of San Jose, called in consultation. Diagnosis according to written statement: "a clear case of phthisis." (He examined the sputum also.)

The doctor told the husband of the patient that in his opinion she would not live much longer than one week. He did not recommend any drugs, but agreed to use oxytuberculin or anything, as the case was far gone. After three months treatment, the patient did her own housework. In six months weighed 122 pounds, or twelve more than for four years.

The asthma has returned only two or three times in 15 months and then only after a heavy meal, and the attack was completely stopped by one treatment of oxytuberculin, within fifteen minutes after administration. The patient feels well, sleeps

ten hours daily uninterruptedly and does her own work. No medicines were used for six months during the treatment with oxytuberculin. Dr. Frassa has examined the patient twice since his first consultation at intervals of about three months, and writes me, "at my last examination some time ago I could still detect some bronchial breathing at the apex of the right lung, posteriorly, but otherwise the patient had made most excellent progress." Four other physicians examined this patient during the first four months of the treatment, each one unhesitatingly saying that it was a case of "tuberculosis."

Is it fair or "unbiased" to call this a case of "asthma"? Does "positive evidence" of tuberculosis only come from an examination by Dr. Smith and none other? Would you submit a case for an opinion to a man who will diagnose the case without an examination?

In every case that I have treated with oxytuberculin there is as much proof of tuberculosis and confirmatory evidence as in the above case, and I challenge proof that the tuberculosis did not exist in every case. Of four cases under my care in which oxytuberculin was used, two made marked improvement, one considerable improvement, one very slight improvement. With Koch's T. R., several cases have made some improvement. My own experience does not lead me to say that oxytuberculin will cure a single case of tuberculosis, nor do I pretend to champion the remedy. Facts are better than statements. Until we find a remedy that will cure every case, it is better to wait for time to reveal the worth of every treatment. Where there are no contra-indications, why not use combined means, medicine, diet, exercise, hygiene, and any available specific treatment? The idea is not to prove the worth of any one remedy, but to cure the patient. Invariably, however, I explain to the patient that no guarantee of cure can be given. Yours respectfully,

D. A. BEATTIE, M.D.

Advertising in the Secular Press.

TECUMSEH, MICH., March 10, 1898.

To the Editor:—In these days of push, of progress, of smokeless gunpowder, of climbing to the pinnacle of fame by every available means, is it not right, yea, is it not the only certain method by which a young and ambitious medical graduate can lift himself bodily into the aerie of success, by advertising his wares in the secular press where he locates, and informing his patrons through the press of his undoubted ability after the following manner?

Dr. Obediah Hayseed, assisted by Dr. Mossback and Dr. Falstaff of Rouge's Hollow, successfully removed a tumor from Mrs. George Gumbo. The patient is doing nicely. Is this not the proper method of becoming eminent with a single bound?

Respectfully yours,

J. F. JENKINS, M.D.

PUBLIC HEALTH.

A New Source of Contagion.—The *Méd. Moderne* relates the case of a child with scarlet fever. As a new dress was required, the mother had a number sent up from the stores and tried them on the child, returning all but the one she decided to buy.

The Favorable Effect of Hygienic Measures on the Eyesight is emphasized by a report recently published detailing the results of the examination of the eyes of school children practiced in Munich two or three times a year for the last sixteen years. The average of vision is constantly rising.

Free Sanatoria for Nervous Affections. Munich is soon to have an institution to receive male cases of functional neurosis, at a nominal sum, one mark a day. A minister, Ringseisen, has placed a couple of villas at the disposition of the committee in charge of the project, and money has been subscribed to build another. As soon as sufficient funds have been collected to

maintain them, they will be put in operation, excluding alcoholics and epileptics.—*Klin. Therap. Woch.*, January 30.

Health in Chicago.—The report for January gives the total deaths during the month as 1835, or 1.13 per 1000. The rate for the corresponding month in 1897 was 1.25. Of these 1835 deaths, 390 were of persons under one year old, and 217 between one and five years. The chief causes were: Pneumonia, 248; nervous diseases, 226; consumption, 202; heart diseases, 124; bronchitis, 92; diphtheria and membranous croup, 68; cancer, 67; acute intestinal diseases, 79; typhoid fever, 29.

Health in Michigan. The report for February gives the diseases most prevalent during the month as rheumatism, influenza, neuralgia, bronchitis, tonsillitis, pneumonia, pleuritis, diarrhea and pulmonary consumption. Compared with the report for January, consumption was more prevalent, being reported at 117 places, while measles was reported at 85 places, scarlet fever at 68, diphtheria at 60, typhoid fever at 53, whooping cough at 27, and smallpox at one place. Compared with the average for February for twelve years, whooping cough, intermittent fever, remittent fever, consumption, scarlet fever, diarrhea and pneumonia were less prevalent.

Sex and Population. The London *Post* in the turbulent wake of the statistician gives some space to the disparity of the sexes, but wrongly credits Egypt as being the only country of the world where the men exceed the women. The avowed number foots up as high as 160,000. Let us dip into the question somewhat. The alleged preponderance of men in the United States is held to be 1,513,510, and in Australia the comparison suffers still more. But by the last Italian census, certainly the most accurate of all, the excess of male over female inhabitants is in the proportion of 50.20 to 49.80. In Greece the percentage of male inhabitants is higher even than it is in Italy, and so it is, too, in Serbia and Roumania. In all the South American countries, with the exception of Chile and Venezuela, men outnumber the women, and this is particularly the case in Brazil and in the Argentine Republic. In England's South African Colonies, in India, and in Canada, as well as in Egypt, the number of male inhabitants exceeds the number of female inhabitants. Egypt's claim to any particular prominence in this matter is based on a very slender foundation at best. By the census previous to the last one it was shown that the total number of male inhabitants was 3,402,000 and the number of female inhabitants was 3,416,000. In a population, therefore, of nearly 7,000,000 the excess of female inhabitants at that time was 14,000, and if since then the scale has been turned slightly and now shows a small preponderance of man, there is certainly nothing in it which particularly calls for any great demonstration of surprise. The only commentary after all seems to be that the masculine element is reasonably content with an unembarrassed struggle for existence.

State regulations of Tuberculosis.—Dr. J. M. Withrow, Health Officer of Cincinnati, in the Ohio Sanitary Bulletin for February, says:

"Fourteen States have bovine laws and regulations, and issued circulars for public instruction with reference to tuberculosis in man, i. e., California, Colorado, Connecticut, Iowa, Maine, Massachusetts, Michigan, New Jersey, New Hampshire, New York, Pennsylvania, Rhode Island, Virginia and Wisconsin. Two States have bovine laws, but do nothing toward stopping the spread of tuberculosis in man, i. e., Minnesota and South Dakota. Tennessee has bovine laws, but can not enforce them for lack of funds, and the Health Board has only issued circulars upon the prevention of tuberculosis in man and beast. The District of Columbia and Oklahoma have a law prohibiting the sale of tuberculous milk, but nothing concerning the disease in man and cattle. Delaware, Indiana, Kentucky, Louisiana, New Mexico, Ohio, Texas and West

Virginia issue circulars of instruction concerning tuberculosis in man, but no steps have been taken concerning bovine tuberculosis. The remaining sixteen States have apparently done nothing to prevent the spread of tuberculosis either in man or beast. In about one-third of the large cities of the United States nothing has been done toward securing the prevention of consumption. . . . In Ohio . . . there is no law to prevent the sale of tuberculous milk, and no means are taken to prevent the spread of tuberculosis among cattle, and so far as tuberculosis in the human being goes, there is no legislation statutory in character upon this subject. . . . The Ohio State Board has issued circulars of instruction on this subject, but their dissemination has not been general enough or frequent enough to create very much public feeling upon the subject. In the city of Cincinnati . . . a board of health regulation has been adopted placing the obligation of physicians to report cases of tuberculosis upon the same plane as cases of diphtheria, scarlet fever and other infectious diseases."

Typhoid Fever at Philadelphia.—There appears to be no doubt in the minds of experts that the Schuylkill River water-supply has been the cause of the high fever rate at that city. That river, near the intakes for Philadelphia, has been shown to be polluted from end to end, and this foul, sewage-laden water is served, unpurified, to the patient tax-payer. East November an accident occurred by which sewage was pumped directly into a reservoir and thence into the city water mains to the consumer; and this accident seems to have been a principal cause of the present outbreak. It is also known that further up the river typhoid is on the increase, and this adds another factor to the cause of the epidemic. But to enumerate these causes is of no avail. The Schuylkill is polluted and every one has known the fact for years. Every one also knows that the practical remedy for the situation is either a thorough filtration or an entirely new plant. Since the beginning of the present outbreak, the first week of last December, 1134 new cases of enteric fever have been reported in the city of Philadelphia, and of this number 675 have occurred during the first four weeks of the new year, or an average of more than 168 new cases weekly up to the present time. As a striking comparison, we may state that during two weeks of the present month New York City, exclusive of Brooklyn, etc., with a population twice that of Philadelphia, reported a total of thirty-six new cases of typhoid, while Philadelphia for the corresponding period reported no less than 366 new cases. To further the comparison, two wards in the infected district of Philadelphia, having a combined total population of 100,000, in one week surpassed the total roll of enteric fever cases reported among the 2,000,000 inhabitants of New York City for a period of two weeks. To make the contrast still plainer, in one recent week in New York City only six new cases of typhoid were reported from the densely populated tenement districts below Fourteenth Street, where the nature of the surroundings and mode of life offer every advantage to the development of filth diseases. On the other hand, the section of Philadelphia in which typhoid is most prevalent is an area not of crowded tenements and of indifferent hygienic environment, but of separate small dwellings, occupied, as a rule, each by a single family, and pronounced by the corps of health inspectors to be of more than average healthfulness.—*Medical News*, January 29.

The American Public Health Association.—The *Public Health Journal* (January) has a personal item respecting the president-elect of the American Public Health Association, Dr. Charles A. Lindsley of New Haven, of which the following is a part: Among the numerous honorable positions heretofore held by Dr. Lindsley, he was a vice-president of the AMERICAN MEDICAL ASSOCIATION in 1871-72, with which society he united

as long ago as 1855. He is one of the oldest living members of the association of which he has lately been chosen president, having joined in 1875. He has made many and important contributions to sanitary and medical literature, to which the annual and other reports emanating from his State board of health and medical society will testify. Of the latter body he was its centennial president in 1892. With the State board he has been connected fully twenty years, and has been its secretary since 1884. With the interests of medical education he has been identified since 1860, and has been for twenty years dean of the Yale University medical faculty. He is a descendant of Francis Lindsley, who came to America in 1666 and settled in New Jersey. He was born in Orange in 1826, and was graduated from Trinity College, Hartford, in 1849, receiving a master's degree in 1852. Then he began the study of medicine and after the close of a term in the College of Physicians and Surgeons, New York, received his degree of M.D. from Yale. Since then he has been a member of the Yale faculty and has lived in New Haven. From 1860 to 1883 Dr. Lindsley was professor of materia medica and therapeutics at Yale, and since 1883 he has been professor of the theory and practice of medicine at that university.

Decline of Typhus Fever in the Cities of Great Britain.—It may be said without exaggeration that five-sixths of the medical profession of this country have never seen a case of typhus fever. And yet the time is not so very remote, say in the sixties, when that fever was a dreaded visitant among the medical internes of institutions, like Bellevue Hospital, New York, that were brought into contact with immigrants from Great Britain having "ship fever," as it was then frequently styled. About the time that this fever began to drop out of the ken of the American profession, along with relapsing fever, the teachers in the medical schools began to recognize the terms "sanitation," "public hygiene," a "preventive medicine," and the like, and to treat briefly of those subjects. This was possibly not much earlier than 1870, and not much earlier, therefore, than the founding of the American Public Health Association. Regarding the decadence of typhus fever, Dr. Bailey of Bilston has prepared the following sketch, a portion of which we quote from the *Lancet*, as follows: "In 1837, typhus fever prevailed in many parts of England, and in 1838 no less than 1271 per million of the population died from it. In the years 1846-48 a frightful epidemic occurred in Ireland on the failure of the potato crop. It spread to England where, in 1848, 786 cases were admitted to the London Fever Hospital alone. In that hospital as many as 14,589 cases were treated during the period 1862-70. In Glasgow, too, the death rate per million for the five years 1855-59 was 1265, and for the five years 1860-64, 1576. These figures show the extremely fatal character of this most formidable disease. Since 1869 this fatality has markedly and continuously decreased, until now it has almost reached the vanishing point. In that year the deaths in England and Wales were 4281, in 1885 they were only 318, and the mean rate for the quinquennium 1891-95 had actually been reduced to 4 per million of persons living. . . . Surely if sanitarians could lay claim to no other achievement they would be entitled by this to an honorable place in the history of the Victorian era."

Caution to be Exercised by Boards of Health in Destroying Property.—The language of the Arkansas statute is that municipal corporations shall have power to cause "any nuisance to be abated." From this and the other provisions relative thereto, the supreme court of the State holds, in the case of *Gaines vs. Waters*, decided Jan. 8, and rehearing denied Feb. 19, 1898, that the city council is authorized to confer upon the board of health power to abate nuisances dangerous to the health of the inhabitants of the city. It takes the view that a board of health is an instrumentality of the city, and that the city has the right

to make general rules to be carried out by the board of health as its agent. The board being but an agency of the city, its acts in reference to the abatement of a nuisance are, in effect, the acts of the city itself. The contention that a city council can not delegate to the board of health the power to determine judicially that a certain structure or other thing is or is not a nuisance, the supreme court goes on to say, has no bearing on the case, for the reason that the council itself has no such power, nor does the board of health in abating nuisances, exercise judicial powers within the usual meaning of such term. There is no requirement that parties interested shall be given notice and an opportunity to be heard, nor does the statute contemplate a judicial hearing before the city council or board of health in matters of this kind. On the other hand, there is no authority to destroy property not a nuisance, and the resolution of a board of health that a house, for example, is a nuisance, the court says, does not make it a nuisance unless it be one in fact, nor is such resolution a judicial determination of that question. This leads the supreme court to make the even more practical, general suggestion, that it follows, therefore, as a matter of common prudence, that in summary proceedings by a city council or board of health to abate a nuisance, when the imposing party has no opportunity to be heard, that great caution should be exercised that property may not be unnecessarily destroyed, and further, for the reason that if it should turn out that a house declared by either of these bodies to be a nuisance was not such in fact, and its removal unnecessary, those removing it might become liable for an action in damages.

Kentucky Local Boards of Health entitled to Compensation.—Section 2055 of the Kentucky Statutes, among other things, provides that, "The local board shall receive such compensation for such services as the county court in which the local board is established shall in their discretion, determine." From this, the court of appeals of Kentucky concludes that the legislature intended that the members of the local board of health should be fairly compensated for the services they are required by law to render. The discretion of the fiscal court with reference to the compensation to which such board is entitled, it further declares, in *Stephens vs. Allen*, Jan. 27, 1898, is not an arbitrary one, but is a sound judicial discretion, and one that can be controlled.

The Water-Supply Laboratory of Brooklyn.—With infinite pains a biologic and chemic laboratory was established at Rockville Center, L. I., for the purposes of a scientific supervision of Brooklyn's supply of drinking water. Under the new régime of the Greater New York, this plant has been wiped out. It had been in operation over a year and was considered by the former health commissioner, Dr. Z. Taylor Emery, as being one of the most sanitary of his accomplishments in his four years' service. As the *Medical News* states, this plant connoted the opinion of those who have discovered that the proper location for an institution of this nature is upon the watershed itself and that the chemic and bacteriologic researches should be accompanied by frequent inspection of all suspected feeders and ponds. The investigations have been conducted by Dr. Hibbert Hill, formerly in the employ of the Louisville Water-Supply Commission, an expert in bacteriology, assisted by Dr. Elms, chemist. Dr. Ezra H. Wilson, who recently resigned from the health department to give his sole attention to the work of the Hoagland Laboratory, was for a time in charge of the Rockville biologic work, but latterly was appointed to the honorary position of consulting bacteriologist. The names of these three officials are signed to an important report of 200 pages setting forth the organization and results of the laboratory. This report is replete with tabular and other technical matters, and will be especially valuable to water-biologists and engineers; it may without exaggeration be characterized as a "State paper" of permanent value. As the new charter of New York City places

the sanitary supervision of water-supplies in the board of health, it is to be hoped that this important function will not be slighted. It is beyond doubt a mistaken policy to neglect this line of sanitary work until the water becomes suspected or polluted, and popular panic and outcry, to say nothing of decimating epidemics, make its resumption necessary.

NECROLOGY.

JOHN DUGAN SKEER, M.D., Chicago, March 7, aged 73 years. Dr. Skeer was graduated from Cincinnati Medical College and the Nashville College of Medicine. Throughout the Civil War he had charge of Hospital No. 9, at Nashville.

SAMUEL H. DISMOND, M.D., Richmond, Va., March 1, aged 44 years. He was graduated from the Richmond Institute in 1879 and as Doctor of Pharmacy and Doctor of Medicine from Harvard University in 1883.

W. O. RODGERS, M.D., Omaha, Neb., March 10, of rheumatism of the brain. Dr. Rodgers was chief medical director of the Woodmen of the World, a member of the AMERICAN MEDICAL ASSOCIATION, and was graduated from the Medical Department of the University of Buffalo in 1883.

WALTER O. RICHARDS, M.D., March 2, aged 78 years. Dr. Richards had practiced his profession in Waterloo and Blackhawk County for forty-three years. He was a member of the County Medical Association, also District, State and National Associations.

S. D. SMITH, M.D., Piqua, Ohio, February 6, age 69 years. He was graduated from the Medical Department of the University of Pennsylvania in 1863; was appointed assistant surgeon in the U. S. Navy and was assigned to duty on the *Brandywine*, which service he left by resignation. He was a member of the AMERICAN MEDICAL ASSOCIATION. At a meeting of the Medical Societies of Miami and Shelby Counties February 9, the following memorial report was adopted:

Resolved, By our Joint Society, that in the death of our associate and fellow member, Dr. S. D. Smith, while bowing in humble submission to the will of our Heavenly Father, that Great Physician before whom we must all appear and whose immunizing power alone can divest mortality of its sting, we have sustained a personal loss and would drop a tear upon the grave of our departed brother and place on record our appreciation of those high and noble qualities of heart and head which make up the life of one so well known as an accomplished physician, whose irrefragable life exemplified the value of a good citizen, who in his social relations was refined, genial and brilliant. One who was a sincere and faithful friend, removed from us at a time of life when many more years of active usefulness were to be hoped for; all who have been associated with him will ever hold in cherished remembrance his varied attainments and those higher moral qualities which rendered him not less endeared than admired.

Resolved, That we ever cherish the memory of our late associate and tender to his bereaved family our warmest sympathy in their great loss.

JAMES E. SHELLENBERGER, M.D.	} Committee.
J. F. GABRIEL, M.D.	
D. R. SILVER, M.D.	
F. M. WRIGHT, M.D.	
O. TYDINGS, M.D.	

JOHN H. MEASE, M.D., licentiate of the Oswego County Medical Society, 1875, died in Oswego, N. Y., March 11, after a practice there of twenty-four years. His wealth, according to the daily prints, was made by ventures in the early days of California, and by sales of horses to the government during the war.

HENRY DAVID KAHLER, M.D., Western Reserve Medical College, 1895, a native of Bolivar, Ohio, died in Shelby, Ohio, where he had recently located, February 20, aged 32 years.

CHARLES H. CALMAN, M.D., died in New York City, March 9, aged 21 years.

GEORGE BOWERS, M.D., Oshkosh, Wis., March 8, aged 29 years.—W. H. BUNKER, M.D., Hartwell, Ohio, March 6.—

Eugene Clark, M.D., New Orleans, March 7.—Charles B. Jennings, M.D., Dubuque, Iowa, March 11, aged 64 years.—Sylvester Laning, M.D., Kingman, Kans., March 4, about 50 years old.—Anthony Weiskopf, M.D., Kenosha, Wis., February 26.—F. B. Wood, M.D., Garrett, Ind., March 1.—J. H. Hauptmann, M.D., Erie, Pa., March 6, aged 34 years.

DEATHS ABROAD.—Sir Richard Quain, Bart., physician extraordinary to her majesty, president of the general medical council and editor of "The Dictionary of Medicine." He was born Oct. 30, 1816, was a fellow of several learned societies and the author of numerous medical and scientific works.

ASSOCIATION NEWS.

Fifty-first Annual Announcement.

OFFICE OF THE PERMANENT SECRETARY,
1400 PINE STREET, PHILADELPHIA.

The Forty-ninth Annual Session will be held in Denver, Colo., on Tuesday, Wednesday, Thursday and Friday, June 7, 8, 9 and 10, commencing on Tuesday, at 10 A.M.

"The delegates shall receive their appointment from permanently organized State medical societies, and such county and district medical societies as are recognized by representation in their respective State societies, and from the medical departments of the Army and Navy and the Marine-Hospital Service of the United States.

"Each State, county and district medical society entitled to representation shall have the privilege of sending to the Association one delegate for every ten of its regular resident members, and one for every additional fraction of more than half that number; *Provided*, however, that the number of delegates for any particular State, Territory, county, city or town shall not exceed the ratio of one in ten of the resident physicians who may have signed the Code of Ethics of the Association."

Members by Application.—Members by application shall consist of such members of the State, county and district medical societies entitled to representation in this Association as shall make application in writing to the Treasurer, and accompany said application with a certificate of good standing, signed by the president and secretary of the society of which they are members, and the amount of the annual subscription fee, \$5. They shall have their names upon the roll, and have all the rights and privileges accorded to *permanent members*, and shall retain their membership upon the same terms.

The following resolution was adopted at the Session of 1888:

That in future each delegate or permanent member shall, when he registers, also record the name of the Section, if any that he will attend, and in which he will cast his vote for Section officers.

Secretaries of medical societies, as above designated, are earnestly requested to forward, *at once*, lists of their delegates.

Addresses.—Presidential Address, Geo. M. Sternberg, Washington, D. C. Address in Surgery, J. B. Murphy, Chicago. Address in Medicine, J. H. Musser, Philadelphia. Address in State Medicine.

Committee of Arrangements.—J. W. Graham, Denver, Colo.

AMENDMENTS TO THE CONSTITUTION AND BY-LAWS.

Offered by W. L. WELLS:

Art. IV.—Officers. Amend to read "Each officer shall hold his appointment for one year, and until another is elected to succeed him."

Offered by H. B. ELLIS:

Art. IX.—Conditions for further representation. "Any State or local medical society, or other organized institution whose rules, regulations and code of ethics agree in principle with those of this Association may be entitled to representation on the advice or agreement of the Judicial Council."

"That the name of the Section on Dental and Oral Surgery be changed to that of Section on Stomatology."

Offered by L. D. Bulkley:

"That all new business shall be introduced not later than the third day of the session."

At the last session it was agreed that all committees having reports of public interest, and particularly matters pertaining to legislation, be instructed to make their reports on the second day at the General Session.

EXTRACTS FROM BY-LAWS.

"The Chairman of each Section shall prepare an address on the recent advancements in the branches belonging to his Section, including suggestions in regard to improvements in methods of work, and present the same to the Section over which he presides, on the first day of the annual meeting. The reading of such address not to occupy more than forty minutes."—*By-Laws*.

"It shall be the duty of every member of the Association who proposes to present a paper or report to any one of the Sections to forward either the paper or a title indicative of its contents and length (not to exceed twenty minutes in reading) to the Secretary of said Section, at least one month before the annual meeting at which the paper or report is to be read."—*By-Laws*.

4.—*The Publication of Papers and Reports.* "Every paper received by this Association and ordered to be published, and all plates or other means of illustration, shall be considered the exclusive property of the Association, and shall be published and sold for the exclusive benefit of the Association."—*By-Laws*.

WM. B. ATKINSON, Permanent Secretary.

Section on Surgery and Anatomy.—All titles for papers in the Section on Surgery and Anatomy must be in my hands by May 1. Inasmuch as my program must be in the hands of the Secretary of the Association by May 7, I must have a week for its preparation. CLAYTON PARKHILL, Sec'y, Denver, Colo.

Section on Ophthalmology. The undersigned would be glad to have the titles of papers for the Ophthalmic Section sent to one of them as soon as possible, in order that they may appear in the preliminary program. The subjects specially set for discussion at the meeting are: The Uses of Electricity in Ophthalmology; and The Treatment of Affections of the Lachrymal Apparatus. Papers on these or any other subjects of special interest to the Section will be welcome. A number of interesting contributions have already been promised and everything points to a most successful meeting. R. L. Randolph, M.D., Secretary, 816 Park Avenue, Baltimore, Md., H. Gifford, M.D., Chairman, 1404 Farman Street, Omaha, Neb.

Notice to all Interested in Neurological Progress.—All who classify themselves under the above caption will confer a favor upon the undersigned by sending a brief memorandum, with accurate reference data attached, of actual progress in neurology and neurology for the past year, or any facts which they may consider so classified, to be epitomized or referred to in his forthcoming Presidential Address to the Section on Neurology and Medical Jurisprudence of the AMERICAN MEDICAL ASSOCIATION at its meeting in Denver in June *proximo*. Communications are also solicited to be presented to the Section either in person or by letter. C. H. Hughes, M.D., Chairman of Section on Neurology and Medical Jurisprudence, 3857 Olive Street, St. Louis, Mo.

Section on Neurology and Medical Jurisprudence—Preliminary Program.—The afternoon of the second day will be devoted to a joint session with the Section on Obstetrics and Diseases of Women for a discussion of The Relation of Pelvic Disease to Nervous and Mental Affections. This will be opened by six short papers, three from each Section. Those contributed by the Neurological Section will be as follows:

Is Pelvic Disease a Cause of Nervous and Mental Affections? by Frederick Peterson, New York.

Are Nervous and Mental Diseases Cured by Pelvic Operations? by F. X. Dercum, Philadelphia.

Nervous and Mental Diseases Following Pelvic Operations, by Harold N. Moyer, Chicago.

GENERAL PROGRAM.

Address of the Chairman, by Charles H. Hughes, St. Louis.

Double Consciousness and the Dual Action of the Brain, by David Inglis, Detroit.

Those Cerebral Neuroses Miscalled Insanities, by Clarke Gopen, Madison, Wis.

Relation of Neurasthenia to the Organic Neuroses and the Acute Psychoses, by James G. Kiernan, Chicago.

The Relation of Neurasthenia to Insanity, by John Punton, Kansas City.

Insanity: Borderland Symptoms: How Best Met, by W. S. Watson, Fishkill-on-Hudson, N. Y.

Neurasthenia: Its Co-relation to the Physiology and Pathology of the Reproductive Organs, by F. Savary Pearce and Harry D. Beyea, Philadelphia.

The Influence of Sexual Disorders upon the Nervous System: Its Nature and Extent, by J. R. Buist, Nashville, Tenn.

Reflex Neuroses in Women, by I. N. Upshur, Richmond, Va.

Uterine Hyperesthesia, by Ephraim Cutter, New York.

Functional Nervous Diseases That Are Associated with Pregnancy, by Samuel Goodman, Boston.

Functional Nervous Disturbances in Pulmonary Invalids, by Sherman G. Bonney, Denver.

Vasomotor Storms, by Frank R. Fry, St. Louis.

Neuralgia and Nerve Cries, by Charles H. Lodor, Chicago.

The Nervous Element in Hyperpyrexia, by C. C. Hersman, Pittsburgh.

Neural Dynamics, by W. J. Herdman, Ann Arbor, Mich.

An Examination of Some So called Faith Curists and Mental Scientists in the Light of Functional Pathology of the Brain, by Louis F. Bishop, New York.

The Stress of Modern Civilization as a Factor in the Causation of Insanity, by Frederic S. Thomas, Council Bluffs, Iowa.

The Question of Inheritance in Degeneracy of the Nervous System, by Ira Van Gieson, New York.

A Form of Degeneracy, by Eugene G. Carpenter, Cleveland, Ohio.

Melancholia, by Frank P. Norbury, Jacksonville, Ill.

Some Experiments in Uric Acid Excretion on a Milk Diet and in Melancholia, by F. Savary Pearce, Philadelphia.

The Result of Blood Examinations in Some Forms of Insanity, in Connection with the Administration of Thyroid Extract, by Samuel Bell, Newberry, Mich.

The Blood Changes in Nervous Diseases, by L. Bremer, St. Louis, Mo.

Toxins of Erysipelas in the Treatment of Insanity, by Oscar A. King, Chicago.

Travel as a Therapeutic Measure in Psychoses, by Richard Dewey, Chicago.

Moral Insanity in Inebriety, by T. D. Crothers, Hartford.

Massage Combined with Psychotherapeutics in the Treatment of Nervous and Mental Affections, by Geo. V. I. Brown, Duluth, Minn.

Electricity an Important Factor in Therapeutics, by W. S. Watson, Fishkill-on-Hudson, N. Y.

Two Cases of Hydrophobia with a Suggestion as to Treatment, by Hugh T. Patrick, Chicago.

Paralysis Agitans, by Sanger Brown, Chicago.

Exophthalmic Goiter, by J. B. Marvin, Louisville.

Hysteria in Children, by J. G. Biller, Cherokee, Iowa.

Aboulia in its Relation to Hysteria, by L. Harrison Mettler, Chicago.

The Opium Treatment of Epilepsy, by Frank C. Hoyt, Clarinda, Iowa.

Modern Treatment in Epilepsy, by Curran Pope, Louisville, Ky.

Symptoms Indicating Organic Nervous Disease, by Howell P. Pershing, Denver.

Paretic Dementia and Tabes, Their Genuine and Counterfeit Varieties, by Arthur E. Miok, St. Louis.

Some Considerations of the Symptomatology in the Diagnosis of Tabes, by J. M. Aikin, Omaha.

Report of a Case of Intra-dural Tumor of the Spine: Removal, Complete Recovery: Exhibition of the Patient; by J. T. Eskridge, Denver.

The Finer Structure of the Nerve-cell in Health and in Disease, by Lewellys F. Barker, Baltimore.

The Neuroglia in Health and Disease; by Maximilian Herzog, Chicago.

The Reclassification of Some Organic Nervous Diseases, by Chas. K. Mills, Philadelphia.

Cerebral Meningitis: Some Suggestions on Diagnosis and Treatment, by D. R. Brower, Chicago.

Apoplexies Without Paralysis; by William N. Bullard, Boston.

Syphilis of the Nervous System as the General Practitioner Sees It, by C. Travis Drennen, Hot Springs, Ark.

Aphasia; With Report of an Interesting Case, by F. E. Coulter, Omaha.

The Orthopedic Treatment of Infantile Spinal Paralysis, by John Ridlon, Chicago.

Lumbo-Abdominal Permanent Drainage in Hydrocephalus, by Alex. Hugh Ferguson, Chicago.

Adiposis Dolorosa, by Augustus A. Eshner, Philadelphia.

The Status of the Medical Expert in the Different States, by Edward B. Angell, Rochester, N. Y.

How Shall Consultations be Conducted by Those Who are to Testify as Experts? by John L. Hildreth, Cambridge, Mass.

The Medicolegal Value of the Roentgen Rays, by Geo. H. Stover, Denver.

The Medicolegal Aspect of Senile Dementia, by W. B. Fletcher, Indianapolis, Ind.

Characteristics of Headaches According to their Origin, by Henry Gradle, Chicago.

Ocular Headaches, by William H. Wilder, Chicago.

Headaches Caused by Errors of Refraction, by J. Elliott Colburn, Chicago.

Some Causes of Wry-neck, by C. M. Hobby, Iowa City, Iowa.

A Case of Acromegaly, by Henry W. Coe, Portland, Ore.

There will also be a symposium on brain tumor, the details of which have not yet been completed.

HUGH T. PATRICK, M.D., Sec'y.

Section on Diseases of Children—Preliminary Program.—Address of Chairmau, by J. P. Crozer Griffith, Philadelphia, Pa.

The Influence of Dystocia in the Causation of Infantile Diseases, by Joseph Eve Allen, Augusta, Ga.

Thyroid Treatment in Early Myxedema and Cretinism in Young Children, by Frederic Bierhoff, New York City.

Blood Examinations in Pediatric Practice, by S. E. Woody, Louisville, Ky.

Of the Value of Eye Symptom in Meningitis, by A. Edward Davis, New York City.

Some Additional Researches on the Poisons Found in Milk and Milk Products, by Victor C. Vaughan, Ann Arbor, Mich.

Tubercular Arthritis in Children, by John Ridlon, Chicago, Ill.

Some Skin Eruptions which are Confounded with Infantile Syphilis, by Charles H. Allen, New York City.

Preventive Treatment of Tuberculosis in Children with Hereditary Predisposition, by John A. Robison, Chicago, Ill.

Fracture of the Clavicle in Children, with Especial Reference to Treatment by a Modification of Sayre's Method, in over 200 Cases, by A. Ernest Gallant, New York City.

Discussion of above by Charles Power, Denver, Colo.

Whooping Cough, R. B. Gilbert, Louisville, Ky.

Eczema in Four Branches of a Family, by Ella M. Patton, Quincy, Ill.

Report of Some Odd Results in the Treatment of Diphtheria with Antitoxin, by Henry Anthony Strecker, Philadelphia, Pa.

Influenza in Children, by James J. Concannon, New York City.

Serum Treatment of Diphtheria, as viewed by the General Practitioner, during the last year, by Alexander McAlister, Camden, N. J.

SOCIETY NEWS.

Florida Medical Association.—The annual meeting of the Florida Medical Association will be held at Jacksonville, Fla., April 26, 1898. R. R. Burroughs, M.D., President; J. D. Fernandez, M.D., Secretary.

The Austrian Congress of Otology discussed the following subjects at the Vienna meeting in February: "Comparative Anatomy of the Labyrinth," "Pigment in the Labyrinth," "Persistent Perforations of the Tympanum," "Traumatic Neuroses," "Cholesteatoma of the Temporal Bone," "Cerebral Deafness," "Anatomy of Acute Tympanitis," "An Automatic Rheostat." Politzer, Gruber and Baginsky were among the speakers.

Congresses Announced.—The fourth International Congress of Physiology will meet at Cambridge, England, August 28 to September 1. The German Congress of Internal Medicine meets at Wiesbaden April 13. Von Ziemssen speaks on medico-legal instruction, Müller and Brieger on intestinal auto-intoxication and antiseptics, and Leo on diabetes mellitus; others on diseases of the cardiac musculature, blood plaques and experimental gastric ectasia. The German Congress of Surgery at Berlin April 13; for particulars address Professor Gurli, W. Keithstr. 6, Berlin. The French Congress of Gynecology, Pediatrics, etc., at Marseilles October 8; president, Professor Pinard. The French Congress of Alienists and Neurologists at Angers August 1. The subjects announced for discussion are: "Post-operative Psychic Troubles," "Arteritis in the Pathology of the Nervous System," and "Transient Delirium from a Medico-legal Point of View." The French Congress of Medicine at Nancy, April 12. Subjects of addresses: "Clinic Forms of Pulmonary Tuberculosis," "Mixed Infections and the Therapeutic Application of Organs with Internal Secretions." The Norwegian Congress of Internal Medicine is announced for August 11 to 13 at Christiania. General secretary, H. Koester, Goeteborg.

BOOK NOTICES.

The Elements of Clinical Diagnosis. By PROF. DR. G. KLEMPERER, Professor of Medicine at University of Berlin. First American from the last (seventh) German edition. With Sixty-one Illustrations. Authorized Translation by Nathan E. Brell, A.M., M.D., and Samuel M. Buckner, A.M., M.D. New York: The Macmillan Company; Chicago: A. C. McClurg & Co. 1898.

As the translators remark, the fact that a work has gone through seven editions in as many years in Germany, is sufficient evidence of its merits, without further comment. They seem to have done their part in an unexceptionable manner. There are no traces in the translation of the involved and difficult language of the original. The book will be, with its convenient form and inexpensive cost, a very acceptable addition to the literature of its subject in our language. There are few works of its compass that are likely to be more serviceable.

Outlines of Rural Hygiene. For Physicians, Students and Sanitarians. By HARVEY B. BASHORE, M.D., Inspector for the State Board of Health of Pennsylvania. With an Appendix on the Normal Distribution of Chlorine, by PROF. HERBERT E. SMITH of Yale University. Illustrated with Twenty Engravings, 5½ x 8 inches. Pp. vi-84. Extra cloth, 75 cents net. The F. A. Davis Co., Publishers, 1914-16 Cherry Street, Philadelphia; 117 W. Forty-second Street, New York City; 9 Lakeside Building, 218-220 S. Clark Street, Chicago, Ill.

This little work is a very useful one and one very much needed. Indeed, the neglected point of sanitation today is the country. In cities the work is attended to by able and well equipped health departments, but rural hygiene is supposed to take care of itself. We bespeak for these "Outlines" of Dr. Bashore a wide circulation and careful attention.

Sexual Neurasthenia (NERVOUS EXHAUSTION), ITS HYGIENE, CAUSES, SYMPTOMS AND TREATMENT, with a Chapter on Diet for the Nervous by GEORGE M. BEARD, A.M., M.D. Edited with Notes and Additions by A. D. ROCKWELL, A.M., M.D. Fifth Edition (with Formulas). Pp. 308. New York: E. B. Treat & Company. 1898. Price \$2.

The editor, Dr. Rockwell, says truly that "the fact that each successive edition of this work has been exhausted more quickly than its predecessor, sufficiently indicates its popularity and right to live."

In this edition is for the first time described what the author terms the "depolarizing" method in the treatment of neurasthenic cases. By this method the force of the positive pole is changed, by the use of a hollow-handled or cup-shaped electrode which, when in use, is filled with some electrolytic fluid, as a weak salt solution or weak solution of soda bicarbonate. This method prevents the pain and undue irritation sometimes felt at the point of contact with one of the ordinary electrodes, no matter how widely separated.

MISCELLANY.

Personal.—Professor William L. Nichol, so long identified with the schools of Nashville, Tenn., as a teacher of medicine, will in future lecture and teach exclusively in the Medical Department of the University of the South, at Sewanee, Tenn.

Broth for Cultivating Microbes.—Miquel recommends the following formula for a cultivation broth in bacteriologic researches: Chapoteau's pepton, 40 parts; gelatin, 4 parts; common salt, 10 parts; wood ashes, 1 part; and 2000 parts of water; the broth is made in the usual way.—*National Druggist*, March.

Retirement of Professor Esmarch. Professor Esmarch of Kiel, one of the veterans of surgery, intends to retire from his professorship very shortly. Esmarch is 75 years old, and has held his chair at Kiel for more than forty years.—*British Medical Journal*, February 12.

An Editor Receives Professorial Honors.—Dr. J. W. McLaughlin of Austin, Texas, has been made professor of practice of med-

icine in the medical department of the University of Texas at Galveston. In accepting this honor, he has had to sever his connection with the *Texas Medical News* as its senior editor. This is a serious loss to our esteemed contemporary. We note, however, that Drs. A. N. Denton and M. M. Smith have been added to its editorial staff, with whose assistance, we feel sure, Dr. Bennett will keep up the standard of the *News*.—*New Orleans Medical and Surgical Journal*.

Paternalism Run Mad.—Representative Parker of Cleveland recently introduced a bill in the Ohio legislature providing for the appointment by the probate court of each county of a board of marriages composed of physicians. To this board, consisting of three members, persons who wish to marry must make application. The board will refuse to grant a license in case either party to the proposed contract has dipsomania, kleptomania, insanity, true or hereditary or resulting from vice; certain blood diseases or tuberculosis. It will charge \$2.50 for each license and out of the fund so made each member will be paid a salary of \$1000. There is provided a method of appeal to the State Board of Health in case of any refusal to grant the license.

Immunity to the Sting of Bees.—Dr. Langer of Bohemia, stated at the recent Congress of German Naturalists and Physicians, that he found the majority of bee-keepers in his district (Ruschowan) acquire a complete immunity to the stings of those insects, while some seem to have enjoyed that immunity from the first, possibly by inheritance. Of 153 nine had always been insusceptible, 118 had acquired the immunity, twenty-six had not. In some cases it was so complete that when intoxicated men had been stung in from fifty to one hundred places with less suffering than is felt by most persons from flea bites. He found the poison to be an animal alkaloid, and not, as is commonly believed, a formic acid. The best treatment is a subcutaneous injection of a 2 to 5 per cent. solution of potassium permanganate, as this salt in the proportion of 1 to 20 destroys this poison.—*The Practitioner*, February.

The So-called Roentgen Lady.—Latest among the marvels of French origin is *La Femme Roentgen*, a woman who is described as being able to read with ease through opaque bodies. Such, at least, is the story. We are told that Dr. Ferroul of Narbonne has found and has introduced this phenomenal lady to his colleague at the Medical Faculty at Montpellier. "All this is quite impossible," exclaimed Dr. Grasset when he was informed of the new wonder. "Well, you will see," was the reply. Then the demonstration was made. The woman succeeded in reading, at a distance, a letter, the envelop of which had been covered with seals and also posted as an additional precaution, and so Dr. Grasset was converted. Some skepticism on the subject is still permissible, nevertheless; yet what a vista of queer possibilities does not this open out, even if *La Femme Roentgen* possesses only a moderate share of the extraordinary qualities thus attributed to her!—*The Parisian*.

Sugar in Mullein Flowers.—Dr. Schneegans, while making periodic examinations of the urine of a diabetic patient, who had been put on a strict diet without carbohydrates, found for a few weeks no sugar, but suddenly a considerable amount was again noticed and continued with regularity, although the diet had not been changed. Inquiries brought to light that the patient regularly drank considerable quantities of strong mullein tea, which had been recommended him as a remedy for Bright's disease. This led the author to repeat the experiments of Rebling, who had found 11 per cent. of sugar in mullein flowers, which would fully account for the sugar in the urine. Schneegans then found in various samples from 9.2 to 11.7 per cent. of invert sugar, and small varying quantities of cane sugar, corroborating the results of Rebling. Traces of an alkaloid were obtained from the seeds.—*Jour. de Ph. in Ap.*

Quantitative Determination of Sugar in Urine.—According to Foerster (*Pharmaceutische Zeitung*) a quantitative determination of the sugar in urine may be made by means of Fehling's solution without the use of an indicator, in the following manner: The solution must be so prepared that 10 c.c. exactly represents 10 c.c. of a 5 per cent. solution of glucose. The limit of reaction when sugar solution in an Erlenmeyer alembic still plainly shows up blue, but when poured into a white 20 gm. glass it is completely colorless. To this end the Fehling solution must be made somewhat stronger than usual, and instead of carrying 34.64 gm. of copper sulphate should contain 35 gm. to the liter. For the determination pour 10 c.c. of the urine into a graduate glass, add 10 c.c. of the glucose solution thereto and fill up with distilled water to the 100 c.c. mark. With this mixture the liter is taken exactly as in pouring in the solution. The amount of the diluted urine used must be divided by 50, and from the quotient subtract 5 gm. The remainder is the percentage of sugar in the urine. The addition of the grape sugar makes it possible to titrate freely without the liquid ceasing to boil. The precipitate settles quickly, and the color shown by the mixture enables the expert to determine the limit of the reaction very closely.—*National Druggist*, March.

Must Assert Privilege in Time.—Referring to the provision of the California code that a licensed physician or surgeon can not, without the consent of his patient, be examined in any civil action as to any information acquired in attending the patient which was necessary to enable him to prescribe or act for the patient, the supreme court of that State says that the privilege is personal to the patient, and is waived when he calls the physician himself as a witness, or when he permits him to give his testimony without making any objection thereto. If the patient once consents to his testifying, he can not, after the testimony has been given, revoke the consent, and ask to have it excluded. Such consent may be either implied or express, further holds the court, in *Lissak vs. Crocker Estate Company*, where it maintains that there was an implied consent when the plaintiff permitted the witness to be examined in full by the defendant without any objection.

The Death-dealing Properties of Modern Ammunition.—The deadly effects of firearms is being steadily increased by the constant improvements which are being made. The *Scientific American* says that the deadly effect upon game of small, metal-covered expanding bullets, with high-velocity smokeless powder, has been recently satisfactorily demonstrated. Modern weapons possess several advantages over the old large calibers in flatness of trajectory, absence of smoke, long range, increased penetration, high velocity, less recoil and light-weight ammunition. The expanding bullet produces invariably an area of laceration greater than ever effected by any projectile before used. Without calculating the effect of the nervous shock, extensive splintering of bone and laceration of tissue are produced. The secret of the deadly effect of these small projectiles lies in their expanding qualities and extraordinary high velocity resulting from the use of smokeless powder, which is only possible when confined in small calibers. These facts are of interest not only to the members of the profession who are notorious Nimrods, when in search of large game, but are of immense practical value to the army and navy surgeon.

Some Examples of Incompatibility.—The fact that many alkaloïds and similar substances frequently give physiologic results different from those expected, suggested to the *Ztsch. f. Krankenfl.* a discussion of these conditions, including a consideration of those medicinal substances, that suffer rapid decomposition and molecular rearrangement and those subject to deterioration during the process of preparation. As examples are mentioned the admixture of silver salts and organic matters; of salicylates with vegetable or mineral acids; sterilization of morphin and

cocain solutions. Ointments are frequently entirely inactive, when containing metallic salts in addition to a salt of morphin or cocain, as the alkaloids are always rendered insoluble by a slight excess of metallic salts. Simultaneous external and internal use of certain medicaments may also exert a disturbing influence on their action. If, for example, an oculist prescribes an ointment containing mercury and the patient takes potassium iodid internally, there will be a formation of mercuric iodid in the eyes, which considerably increases their inflammation. Quinin is not infrequently prescribed with substances containing tannin, an insoluble tannate of quinin being the result. Quinin is also slowly precipitated by potassium bromid. In the cases of iodin and bromin the reactions with quinin are not always simple, but at times these bodies enter directly into the molecule and change not only the structure, but also the physiologic properties and are liable to change it even into toxic bodies. During the sterilization of morphin solutions there is a liability, especially when the temperature is too high, of forming apomorphin, an alkaloid of totally different therapeutic action. A similar change may take place under like condition in the sterilization of cocain solutions.—*Ph. Post*, in *Pharmaceutical Era*, March 3.

Supreme Court of United States on Suicide of Sane Insured Person.

—A most important decision, bearing on the legal effect on life insurance of a policy holder committing suicide while sane, was rendered by the supreme court of the United States, Jan. 17, 1898, in the case of *Ritter vs. the Mutual Life Insurance Company*. Here it approves an instruction of the jury that if the insured understood what he was doing, and the consequences of his acts to himself and to others (that is, if he understood, as a man of sound mind would, the consequences to follow from his contemplated suicide, to himself, his character, his family and others, and was able to comprehend the wrongfulness of what he was about to do, as a sane man would), then he was to be regarded as sane; otherwise, not. And if experience justifies the view that an application for a policy would be instantly rejected if expressly providing that the company would pay the sum named if the insured committed self-destruction, being at the time of sound mind, the supreme court insists, it would follow that a policy stipulating generally for the payment of the sum named in it upon the death of the insured, should not be interpreted as intended to cover the event of death caused directly and intentionally by self-destruction while the insured was in sound mind, but only death occurring in the ordinary course of his life. But the court goes still farther and holds that if a policy—taken out by the person whose life is insured, and in which the sum named is made payable to himself, his executors, administrators or assigns—expressly provided for the payment of the sum stipulated when or if the insured, in sound mind, took his own life, the contract, even if not prohibited by statute, would be held to be against public policy, in that it tempted or encouraged the insured to commit suicide in order to make provision for those dependent upon him or to whom he was indebted. Nor does it consider that the case is any different in principle when such a policy is silent as to suicide, and the event insured against—the death of the insured—is brought about by his wilful deliberate act when in sound mind.

Coroner's Verdicts not to be Considered in Civil Cases.—Upon a rehearing, in the case of the *Germania Life Insurance Company vs. Ross-Lewin*, the supreme court of Colorado reverses the position it first announced, and rejects the construction which the supreme court of Illinois has put upon a statute similar to that of its own State and upon which statute the latter one was previously modeled, relative to the use of coroner's verdicts. It now takes the ground, Dec. 20, 1897, that the purpose of the coroner's inquisitions is merely to furnish the foundation for a criminal prosecution in case the death is

shown to be felonious, and are of extrajudicial character. It says that in case of death under suspicious circumstances, or resulting from accident, the rule permitting inquisitions to be used in evidence would result in a race and scramble to secure a favorable coroner's verdict that would influence, and perhaps control, in case suit should be instituted against life insurance companies upon policies of insurance, and in cases of accidents occurring as the result of negligence on the part of corporations operating railways, street-car lines, mining for coal or the precious metals, etc. Law writers of late have frequently animadverted upon the carelessness with which such inquests are frequently conducted, and to allow inquisitions to be used in a suit between private parties upon a cause of action growing out of the death of the deceased, continues the court, would be to introduce an element of uncertainty into the practice, which, it thinks, would be contrary to public policy, and pernicious in the extreme; and for these reasons, the court concludes, upon careful consideration, it says, that the safer and better rule is to exclude such inquisitions.

Hypnotism Before the Court.—In the supreme court of California, in the case of the *People vs. Ebanks*, the ruling of the Trial Judge in reference to the effects of hypnotism upon the defendant, are interesting. The decision was reviewed by the supreme court of California. In this case a witness was called by the defendant who was charged with murder and an offer was made to prove by him that he was an expert hypnotist, that he had hypnotized the defendant and that when hypnotized the defendant had made a statement to him in regard to his knowledge of the affair, from which statement the witness was ready to testify that the defendant was not guilty and that defendant denied his guilt while in that condition. The Trial Judge sustained an objection to the testimony. He said: "The law in the United States does not recognize hypnotism. It would be an illegal defense and I can not admit it." Commissioner Searles, who prepared the opinion of the supreme court of California, wherein it, Aug. 23, 1897, affirmed the judgment of conviction of murder in the first degree, said "We shall not stop to argue the point, and only add the court was right." Commissioners Belcher and Chipman concurred. Justice McFarland said: "I concur in the judgment and in the opinion of Commissioner Searles, but what is said in the opinion on the subject of hypnotism must be taken as applicable to the testimony offered on that subject in this case, which was clearly inadmissible, and not as covering the whole subject. It will not be necessary to determine whether or not testimony tending to show that a defendant committed the act charged while in a hypnotic condition is admissible until a case involving that precise question shall be presented." In this utterance, Justices Henshaw and Van Fleet concurred.—*Medico-Legal Journal*, December.

Qualification of Expert as to Poisons.—Notwithstanding that the supreme court of Colorado says it is seldom that a witness is presented whose general competency, not only in the practice of medicine, but in toxicology, is so well established as was that of Dr. Eskridge upon the trial of the case of the *Germania Life Insurance Company vs. Ross-Lewin*, the trial court refused to receive his testimony with reference to the effects of cyanid of potassium upon the human system, for the reason that he had had no actual experience with poisoning from cyanid of potassium. This ruling the supreme court pronounces clearly erroneous. It says new poisons are constantly being discovered by scientists, and under the rule announced by the district court all inquiry as to the result of such new poisons upon the human system from experts would be excluded. In fact, under that rule, expert evidence would be excluded in all except those cases in which some of the usual and well-known poisons were resorted to. And the supreme court suggests that it would offer a premium to the ingenuity of criminals and others in the

selection of rare and unusual poisons to destroy human life. For these reasons, the court declares the rule entirely too technical, and not supported by reason or authority. Moreover, while in some States it has been held that the decision of the trial court upon the competency of a witness to testify as an expert is conclusive, the supreme court of Colorado takes this opportunity of declaring for the contrary rule as supported by the weight of reason and authority and because it has the sanction of the supreme court of the United States.

Better Have Your Family Physician.—

Jest keep the heart a-beatin' warm,
Be kind ter every feller;
Look fer the rainbows in the storm,
But—carry yer umbreller!

Be brave ter battle with the strife,
Be true when people doubt you;
Don't think that money's all in life,
But—carry some about you!

An' when it's time ter shuffle off,
An' you have done yer mission,
Jest put yer trust in Providence,
An' call a good physician!

—*Atlanta Constitution.*

Recent Experiences with Cataract Operations.—At the recent Moscow Congress, Knapp of New York reported 1050 cataract operations, of which 400 included all complicated cases. The method of operation was usually a simple extraction without iridectomy, and the incision at the border of the transparent cornea almost half its extent. The capsule was opened with the cystitome to the extent of 5 or 6 mm. in the upper part of the iris, so that the torn pupillary edge of the iris and the wounded capsule should not touch. Pressure at the lower part of the cornea easily delivers the lens, but contact of the border of the lid and the corneal wound should be avoided. Both eyes are bandaged afterward and the dressing changed after twenty-four hours, when any prolapse of the iris can be disposed of. Reaction of an inflammatory nature was limited to six cases of slight iritis, two cases of partial wound infection and four cases of purulent infection of the cornea. In 355 operations prolapse of the iris occurred fifteen times (7.6 per cent.) and was successfully treated by iridectomy. Secondary operations were done in 40 per cent. of the cases. In three cases glaucoma following discission was observed. Recovery was obtained by means of iridectomy, eserine and morphine. In the last 400 cases good vision was obtained in 93 per cent., fair in 4.5 per cent. and total failure in 2.4 per cent.—*Archives of Ophthalmology.*

Therapeutic Value of Spleen Extract.—The *Edinburgh Medical Journal* for February, contains the results of an investigation extending over two years and establishing the therapeutic value of this extract. Briefly, "it aids digestion and nutrition, increases the cutaneous activity, stimulates the glandular activity of the skin, etc." In the first class of cases, chronic inertia, mental and physical, after a year's treatment the mental result was *nil* in a few, slight improvement in a few and recovery in two. The second class included recent cases of insanity due to physical exhaustion and the results were more prompt, first physically, then mentally, the majority being improved and some completely restored. The effect on the pulse and temperature, the bowels and urine, is yet to be determined definitely; in some the appetite improved, in more the digestion; the weight curves varied, increase of weight being the rule; in all the women there was increase of hemoglobin and red blood cells with one exception; color and warmth of the skin with softness and elasticity was noted; mentally, exhibition of temper was noted in both sexes, more so in the males. The author had previously used thyroid extract with no success in these mental cases. He believes that, "spleen extract, if less phenomenal in its effects than thyroid, is conducive to more lasting results, that it is surer, and still more important, exceedingly

safe," but much smaller doses are sufficient to produce pyrexia, etc., especially after use of the etherial extract.

Suits by Both Physician and Patient against Railway Company.—One of the points sought to be made in the case of Smith vs. the Chicago & Northwestern Railway Company, an action brought to recover payment for medical services rendered in the treatment of an injured employee of the company, was that the plaintiff physician was estopped by having given testimony showing the service rendered and the value thereof, in an action brought against the company by the former patient, in order to enable the latter to recover therefor. On the trial, the jury were instructed that if the physician was a witness in the other case, and for the purpose of enabling his former patient to recover against the railway company, he gave testimony that he was the physician in attendance, and performed the services, and of their value, thus enabling the former patient to recover of the company for such services, he, the physician, was estopped to recover in this suit of his own. But this was followed by another instruction that if the jury believed that at the first trial, and when the physician was examined as a witness, in answer to the question with reference to his bill for services he said: "I have a suit pending against the company for my services, and I expect to collect for my services from the defendant," or words of a similar effect or import, then there would be no estoppel. This, the supreme court of Iowa holds correct, December, 1897. It says that the doctor owed the railway company no duty, when asked, on the first trial about his services, to decline to answer, and inform the court that he had a suit pending for such services. He was a witness in court, and, in a sense, under the direction of the law. The defendant company was present, with full opportunity to insist upon a disclosure of the facts; and if the witness gave them, and, in so doing, it was made to appear that he was a claimant for such services himself, the court maintains, the basis for an estoppel against him in his own suit failed.

New York Skin and Cancer Hospital.—The New York Skin and Cancer Hospital now has a proper building. For fifteen years it has occupied a dwelling house, 243 East Thirty-fourth street, which was altered over, but on March 5 the new hospital building, Second Avenue, corner Nineteenth Street, was opened with appropriate ceremonies. After a few introductory remarks by the president, Mr. J. Cleveland Cady, Dr. A. Jacobi, president of the medical board, made an address, dwelling on the necessity and value of special hospitals and the work of this, the only institution of its kind in the United States. Dr. L. Duncan Bulkley then made an address, reviewing briefly the origin and early history of the Hospital, and its work during the fifteen years of its existence. He called attention to the fact that the old city of New York had grown at the rate of 50,000 inhabitants a year for the past ten years, and suggested that the hospital accommodations had not kept pace with the growth of the city. He mentioned that most of the other special departments of medicine had special hospitals, but until the establishment of the New York Skin and Cancer Hospital there had been none of the kind in this city or country. He instanced the large provision made for skin diseases in Paris, Vienna, Berlin and all the cities of Europe, Great Britain having twelve special hospitals of this kind. Beginning in a very small way and with no endowment or pledged support, the Hospital had received \$375,000 during the past fifteen years, of which \$75,000 had come from board of patients, and also of drugs to out-patients. Of the \$300,000 contributed from outside, the hospital now had \$25,000 invested for five endowed free beds, and had paid \$150,000 for the new building, which was free of debt; but, as it had no permanent or definite income, he earnestly asked gifts and moral support from those present. During the fifteen years the Hospital had treated 25,031 patients, of which 22,159 had been out-patients,

who had made 118,154 visits to the Hospital, and for whom 132,263 prescriptions had been written and filled. The in-patients had spent 165,077 in the Hospital. He called attention to the value of the Hospital as an educational center, instancing that thirty young men had been internes and had acquired a knowledge of these diseases second only to that obtained by prolonged study abroad. He also stated that it was proposed to have clinical lectures in the Hospital, free to physicians, which were to be further illustrated by a collection of Paris models and colored plates which had been loaned to the institution. The new building is a modern fire-proof structure of four stories and basement, containing about sixty beds for patients. Of these, seven are in private rooms. On the top floor there is a modern operating room, well equipped, the Worden ward for children and most of the private rooms. On the next two floors are four wards for male and female patients with diseases of the skin and cancer. On the ground floor is the large out-patient room, with consulting rooms, pathologic laboratory, drug room, office, reception room, etc. In the basement there is a complete set of baths, including Turkish, Russian, needle and plunge; besides the kitchen, laundry, dining rooms, etc. The lighting, heating and ventilation are of the most approved kind.

Wanted.—We desire to secure a copy of No. 11, Vol. iii, of the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION for completion of above volume for a foreign library. Anyone having this number to spare will confer a favor by returning same to this office and we will remit charges.

Acute Otitis and Mastoiditis Cured by Intercurrent Erysipelas.—Stein reports a case so severe that trephining of the apophysis was decided upon, when suddenly the patient was attacked with erysipelas of the nose, extending to the mastoid region and the diseased ear. The attack lasted two weeks and the other trouble vanished with it.—*Semaine Méd.*, December 15.

Histo-psychology.—In describing two cases that combined the two syndromes of meningism and catalepsy, Dupré ascribes them to two factors, a grave toxic-infection and a psychopathic predisposition. In toxic encephalopathy the form of the accident is determined at least as much by the psychopathic disposition of the subject as by the pathogenic properties of the poison (uremic). This explanation will probably be confirmed by the new science now being evolved by our progress in histologic technique and psychologic analysis which Soury calls histo-psychology.—*Presse Méd.*, January 22.

Histologic Investigation of the Prostate after Castration, etc.—Extensive experimental research at the Histologic Institute at Nancy in regard to the atrophy of the prostate after castration, vasectomy and the new method of intra-epididymitis injection of a 20 per cent. solution of zinc chlorid resulted in evidences of regression of the glandular substance with considerable development of the interstitial conjunctiva, and the size of the gland very much reduced, especially in the pig. These results were invariably found after castration and also after the sclerogenic injections, not so constantly after vasectomy (sheep, sheep, pigs, dogs, guinea pigs).—*Presse Méd.*, January 22.

Cleanings.—An exhibit of universities is to be one of the features of the Paris Exposition.—Professor Ruggi of Modena recently performed his thousandth laparotomy.—Unilateral, repeated pains in the articulations, myalgia or neuralgia may prove the precursors of hemiplegia; especially important in the diagnosis if the vascular system shows a predisposition to the affection (*Journ. de Méd. et de Chir.*, 1898, No. 1).—If in convalescence from pneumonia the valvular sound assumes a "smothered" tone, becoming later "smothered and hard," it is an indication of incipient ulcerous endocarditis, which should receive prompt treatment without waiting for further

indications (*Gazz. d. Osp. e d. Clin.*, January 20).—Jean Pasteur is said to receive \$110 a day from Cornelius Vanderbilt, for his medical services, accompanying him on the yacht *Catania*.—The viceroy of India has sent to England for more medical assistance. He asks for eight physicians, two women physicians and twenty-five nurses.

Anatomic Alterations in the Genital Organs after Sexual Operations to Relieve Hypertrophied Prostate.—B. Floderus contributes an article to the *Nordiskt Med. Ark.* of January 10, based on the necropsy of thirty-six cases previously operated. In twenty the examination was both macro- and microscopic (testectomy fourteen, vasectomy five, combined one). He adds a number of illustrations which show that these operations fail to produce any alterations in the organized tissue of the prostate. The decrease in the size of the prostate, which, he adds, is inconstant and seldom equal to the extent of the hypertrophy, is not due to any alterations in the organized tissues but is rather to be attributed to a diminution in the elements circulating in the organ, the blood and the lymph. The importance of this diminished congestion from the functional point of view is less apparent in the prostate proper than in the prostatic portion of the urethra and neck of the bladder. In normal prostates a genital operation may induce alterations in the organized tissue, but this he considers impossible in senile hypertrophy to any appreciable extent. The evidences of fatty degeneration, etc., are no more than is observed in non-operated hypertrophied prostates.

Gladstone's alleged indifference to Sanitary Legislation.—An old medical friend of Mr. Gladstone and who had been somewhat of a sanitarian all his life, is wont to complain that he has never been able to enlist the attention of that mind of large and multitudinous interests in questions of sanitary reform, questions of infinitely greater importance to Englishmen than the troubles of Bulgaria and Armenia. This venerable physician has come to the conclusion that sanitation lacks in those "showy" qualities that lead public men to become the champions of subjects that excite the *vox populi*. The best way to get politicians to consider the public health is to educate people up to that point where the latter will begin to insist upon having that theme put as "a plank in every platform." When votes are to be caught by pledges on behalf of sanitary reforms and administrations are turned out for not redeeming such pledges, then will the statesman arise to the needs of the commonwealth, and we will view the upbuilding of a national Department of the Public Health. It is not difficult to imagine how different might have been the position of public medicine before the world if Mr. Gladstone had, in the early part of his career and later, adopted sanitation as one of his war cries. It can not be said that his attention was not properly called to the subject, for his lively foe, Disraeli, in the 70's, threw down the challenge in a proposition that speedily sped around the English-speaking world, to the effect that "the first consideration of a minister should be the health of the people."

The Semeiologic Value of Abnormal Reactions of the muscles and nerves, was the subject of an address by E. Doumer at the Brussels Congress of Neurology. He asserts that it is only in quite exceptional cases that it is possible to excite exclusively the muscular fiber. In most cases the muscular reactions obtained by applying electric excitation to selective points on the muscles are due mostly to excitation of the terminal filaments of the motor nerves. The term "exploration of the muscles," used so frequently in electro-diagnosis, is therefore incorrect. The reaction of the muscle to the excitation of the nerve, shows that this excitation is transformed at the exciting point into a nerve wave which in its turn acts upon the muscle. After studying the abnormal reactions hitherto described

(reaction of degeneration, of compression, of the diathesis of contractions, myotonic, etc.), which are in reality electric syndromes formed by the elementary reactions, he arrives at the following important conclusions in regard to these elementary reactions: Faradic and also voltaic hypo-excitability may depend upon an alteration in the reacting organ (muscle), as well as upon an alteration of the excited nerve. It always corresponds to an alteration in the nervo-muscular system situated *below* or *at* the point excited. Among the qualitative modifications of voltaic excitations he asserts that what he calls "Erb's reaction" always corresponds to a more or less profound alteration of the peripheral motor neurons at the very point of the excitation. It is absolutely independent of the lesions which may be situated above or below this point. The other elementary reactions are still too little known for positive clinical deductions. He urges the adoption of methods of exploration in electrodiagnosis which will determine the characteristics of the excitation, and the curve of the reaction, and suggests that the principles necessary for the establishment of such methods may be found in Professor d'Arsonval's remarkable works.

Fatality Following a Controversy Between Medical Men.—A letter from the University of Bonn recites a tragedy following a difference between surgeons. An armed encounter between members of the medical profession at this the close of the nineteenth century was certainly not to be anticipated, but the old saying that it is always the unexpected which arrives has once more been verified. It is only too true that a duel was recently fought at Bonn, the combatants being both medical practitioners, and most unfortunately one of them met with his death from a penetrating wound of the thorax. It seems that two of the assistants of a surgical clinic named Reusing and Fischer, had a violent altercation over a professional matter, the former accusing his colleague of malpractice in the conduct of an operation, and as apparently there was no older and wiser person at hand to pour oil on the troubled waters a hostile meeting ensued, with the above mentioned deplorable result. That duels should still survive on the Continent, especially in military circles is perhaps not to be wondered at under the existing regime, but happily the vast majority of medical men of all nationalities are the possessors of well balanced minds, and recourse among them to the *argumentum baculinum* for the adjustment of technical disputes must be an altogether exceptional occurrence. Complaints are often heard of the overcrowding of the medical profession on the other side of the channel, but of all deplorable methods the slaying of one's confrère is surely the least philosophic. A duel at the present day is an anachronism. As a mode of settling scientific controversy it is not only out of date, but also about the most illogical procedure conceivable. Killing an opponent does not prove the survivor's case; while the gratification of an ignoble feeling of personal resentment is dearly purchased at the expense of lifelong remorse. The principals in a duel are blameworthy, but for them there are excuses, seeing that most human beings are more or less passionate by nature. For the seconds, generally speaking, there is absolutely nothing to be said. They are simply the abettors of a crime in which they run no bodily risk, and it is against them that retributive justice should be mainly directed. If seconds would only consider the heinousness of their position, there would soon be an end of dueling.

Ohio Law Constitutional.—The constitutionality of the Ohio law passed Feb. 27, 1896, "to regulate the practice of medicine in the State of Ohio," was attacked in the case of France vs. State. One objection made to the statute was that, by those provisions which authorize the medical board, for the causes therein mentioned, to refuse or revoke certificates of qualification required of physicians before they are entitled to practice in Ohio, and provide for an appeal to the governor and attorney

general, it assumes to confer judicial power which, under the State constitution, belongs exclusively to the courts. Undoubtedly, says the supreme court of Ohio, Oct. 26, 1897, the authority conferred by the provisions referred to includes the power to examine into and decide questions requiring the exercise of judgment, such as might not inappropriately be conferred on a court. Nevertheless, it holds that the power conferred on the board is administrative in character, and not judicial, within the meaning of the constitution; nor made judicial by the circumstance that an appeal is allowed from its decisions to the governor of the State and the attorney general. It further holds that the statute is prospective in operation, and in no respect obnoxious to section 10 of article 1 of the Federal constitution, which forbids the enactment of *ex post facto* laws and bills of attainder by the States. Neither does it consider that the regulations adopted by this statute infringe upon the privileges and immunities guaranteed by section 2 of article 4 of the Federal constitution to citizens in the several States, nor abridge those secured to citizens of the United States by the fourteenth article of amendment of that constitution. It is competent, the court declares, for the State, under its power to provide for the welfare of its people, to establish needful regulations, and impose reasonable conditions, calculated to insure proper qualifications, both with respect to learning and moral integrity, of persons desiring to engage in the practice of medicine in the State, and require compliance therewith by such persons before they shall be permitted to practice within the State. Of that character, it pronounces the regulations adopted by the statute in question, which it accordingly holds constitutional and valid.

Societies.

The following recent meetings are noted:

California.—Fresno County Medical Society, Fresno, March 1.

Connecticut.—Bridgeport Medical Society, March 2.

Illinois.—Chicago Pathological Society, March 14; East St. Louis Medical Society, March 7.

Indiana.—Bartholomew Medical Society, Columbus, March 1; Marion County Medical Society, Indianapolis, March 1; Monroe County Medical Society, Bloomington, March 8; Tippecanoe County Medical Society, La Fayette, March 2; Vigo County Medical Society, Terre Haute, March 3.

Iowa.—Semi-annual meeting of the Medical Society of the Missouri Valley, Red Oak, March 17.

Massachusetts.—Everett Medical Society, Boston, March 1.

Michigan.—Grand Rapids Medical Society, February 28.

Minnesota.—Minnesota Academy of Medicine, St. Paul, March 2; Ramsey County Medical Society, St. Paul, February 28.

Missouri.—St. Louis Medical Society of Missouri, March 12.

New York.—Binghamton Academy of Medicine, March 3; Broome County Medical Society, Binghamton, March 3; Herkimer County Medical Society, Herkimer, March 1; Hornellsville County Medical and Surgical Association, Hornellsville, March 1; Queens County Medical Society, Jamaica, March 1; Syracuse Academy of Medicine, March 8; Utica Medical Library Association, March 7.

Ohio.—Lucas County Medical Society, Toledo, March 4; Tri-county Medical Society, Conneaut, March 1; Union Medical Society, Chicago, March 14.

Pennsylvania.—Luzerne County Medical Society, Wilkesbarre, March 2; York County Medical Society, York City, March 3.

Wisconsin.—Waupaca County Medical Society, Manawa, March 5.

Denver.

THE MEETING OF THE AMERICAN MEDICAL ASSOCIATION.—The Denver and Arapahoe Medical Society, to whose successful efforts the State of Colorado owes the honor of securing the next Convention of the AMERICAN MEDICAL ASSOCIATION will not be found dozing when the jolly Esculapians are here. It is not expected that the members of the ASSOCIATION, learned and devoted to pure science as they are, shall subsist on pure air, glorious sunshine and mountain views. The people of Colorado, the medical men as a body, with the Denver and Arapahoe Medical Society at the head, intend to also add to the spir-

itual pleasures those of the flesh. The society has appointed a committee on entertainment consisting of men versed in that particular branch of science, and they will fulfill their onerous duty to the satisfaction of all. The entertainment to be given by the local medical society will be one of the prominent features of the convention, and the palate of the most fastidious will never forget the event.

Dr. CARL JOHNSON, vice-consul and port surgeon. Dr. Johnson has sailed for Amoy, China, at which port he will serve in the above double capacity.

Cincinnati.

THE mortality report for the week shows: Still-births, 8; zymotic diseases, 13; phthisis, 12; other constitutional, 6; local, 59; developmental, 11; violence, 6; under one year, 21; between one and five, 15; total, 107; annual rate per thousand 13.73; preceding week, 117; corresponding week, 1897, 103; 1896, 120; 1895, 123.

Dr. W. E. LEWIS announces a class in anatomy for students in medicine, dentistry, art, physical culture, calisthenics and obstetrics, open to both sexes, beginning April 4; class to meet Monday, Wednesday and Friday from 8 to 9 P.M., at the Cincinnati College of Medicine and Surgery.

THE ACADEMY OF MEDICINE held their annual election March 7, and the following officers were chosen: President, Louis Schwab; vice-presidents, J. C. Oliver and Estella Riley; treasurer, S. E. Allen; secretary, W. H. Crane; financial secretary, M. A. Tate; corresponding secretary, F. E. Kugler; trustees, A. I. Curson, N. P. Dandridge and J. T. Whittaker.

THE representatives of the several medical societies have joined in an attempt to secure an amendment of the present medical law. The intention is to increase its present effectiveness by making it more stringent and more in conformity with the medical laws of New York, New Jersey and Pennsylvania which are much more rigorous than the twenty other States having a specific law. The outcome of this proposed amendment will be to practically make the Board of Registration a board of examination for the licensing of all practitioners of medicine, whether graduates or not.

THE ANNUAL REPORT of the State Board of Registration and Examination gives the following summary: Total number of certificates issued, 8231; to graduates, 7521; to legal practitioners, 697; by examination, 13; number rejected, 339; graduates, 121; legal practitioners, 204; examination, 14. Cash balance on hand at beginning of the year, \$5,460.56; disbursements, \$10,429.87; total deposited with State Treasurer since passage of the Musgrove Law, \$25,919.02.

Detroit.

WAYNE COUNTY MEDICAL SOCIETY.—At the regular meeting of this society, March 10, Dr. W. C. Stevens read a paper on "Habitual Abortion." The Doctor took up the subject only in so far as it relates to those cases of habitual abortion which result in women who show no signs of hereditary taint, or any constitutional dyscrasia, and who have no lesion of the parturient canal. He reported the history of a case occurring in his own practice of a woman, who during her twenty-five years of married life, had been pregnant thirteen times. Seven times she aborted and six children were born to her at full term. The etiology of the case was very obscure, as there was no apparent cause for the abortions, either local or general. During treatment her gestation would go on to full term, but if the treatment were remitted abortion would supervene. The treatment recommended by the Doctor in this and similar cases was the absolute avoidance of heavy work, hygienic measures, properly fitting and light garments (the skirts being supported from the shoulders), plenty of sleep, and daily sponge baths. The medicinal measures consist in the use of mild laxatives when necessary, tonics, assafoetida, Jamaica dogwood and black haw. Dr. Lucy J. Utter read a paper on the subject of the "Constitutional Causes of Abortion," referring particularly to syphilis as an etiologic factor. Dr. C. D. Aaron presented a paper on the "Relation of Hemorrhage of the Stomach to Menstruation." The Doctor stated that hemorrhage from the stomach may occur in gastric ulcer, carcinoma, heart disease, portal obstruction, cirrhosis of the liver, scurvy, yellow fever, acute yellow atrophy of the liver, rupture of an aneurysm and

active hyperemia. To the last named class belongs hemorrhage from the stomach co-existent with menstruation. The Doctor concluded that patients who suffer from gastric hemorrhage always present symptoms of indigestion, and that therefore when a patient exhibits symptoms of indigestion during a menstrual period in which the flow is scanty, gastric hemorrhage must be suspected even though vomiting does not occur.

Philadelphia.

COLLEGE OF PHYSICIANS.—"A Consideration of the Real Value of the Cold Bath Treatment of Brand in Typhoid Fever" was the title of a paper by Dr. Hobart A. Hare, which led to a spirited discussion at the meeting held on the 2d inst. The fact that the author had himself recently suffered with a severe attack of typhoid and had enjoyed (?) a personal experience of the Brand method, in addition to the fact of his prominent position as a writer and teacher of therapeutics, gave special interest to the expression of his views upon this important subject. He said that a very decided decrease in the mortality of typhoid fever had unquestionably occurred of late years, but much of this is undoubtedly to be ascribed to improvements in nursing, in sanitation, and in other methods of treatment, which are now employed in conjunction with the Brand system. In reply to his own query of how much of the improved mortality is fairly to be ascribed to the baths, he said that the difference between 10 per cent. mortality when the baths are not given and 7.5 per cent. when the baths are given, or 2.5 per cent., might be fairly credited to the cold bath treatment. Against this he placed the facts that the course of the disease is prolonged, hemorrhages and relapses appear to be more frequent, and perforations occur in the same proportion and certainly are not lessened in frequency. While admitting the usefulness of the bath in appropriate cases, he deprecated its too frequent employment, protesting against routine management. In the great majority of cases the early use of calomel, symptomatic treatment, and moderate stimulation, with cold sponging, not merely to the extremities but the back especially, to reduce pyrexia, would prove sufficient, with the aid of proper diet and judicious nursing, to bring about recovery of the patient, but each case should be considered as an individual one and treated on its merits as an individual. In the discussion, the advocates of the Brand method were decidedly in the majority. Dr. Wm. Osler said that at Johns Hopkins, out of 684 cases treated, the mortality was 8.1 per cent. and he was convinced that if generally used throughout this country, the Brand method would prevent five or six deaths out of every hundred cases of typhoid fever, cases which in his opinion could not be saved by any other known method of treatment. Dr. James Tyson stated that there is not only a decided reduction in the mortality rate, but there is also less delirium and less diarrhea, and the type of the disease is made milder. He had not seen any harmful effects and preferred the routine employment, on account of the fact that although discrimination is desirable, it is difficult and not always practicable. Dr. John H. Musser endorsed the preceding speaker's remarks and said that he had never witnessed any ill effects, but on the contrary had observed relief from threatening complications. He advised modification of the cold bath in certain cases. Dr. J. P. Crozer Griffith said that at the Children's Hospital he is accustomed to place the little patients at first in a warm bath (95 degrees F.) and then to gradually reduce the temperature (to 85 degrees) and claimed great reduction in the mortality. Dr. H. C. Wood, basing his remarks on twenty-five years experience with this method, stated that each year he only confirms him the more as to the value of the cold bath treatment of typhoid fever. He considered the object of the treatment to be the abstraction of heat as rapidly and with as little violence as possible to the patient. He thought that it might have contraindications, especially when begun late in the course of the fever, and in asthenic cases. Dr. S. Solis Cohen said that he finds the application of the ice bag over the abdomen a useful expedient to reduce temperature. In reply to Dr. A. V. Meigs, who criticized the method and denied that it accomplished all that had been claimed for it by enthusiastic advocates, Dr. A. A. Eshner said that Brand did not advocate the indiscriminate and routine employment of cold baths, but on the contrary their systematic and discriminate employment. Dr. T. M. Balliet claimed that where bathing with cold water was not practicable, as among the very poor, he had exposed the fever patient to cold air, with the same object in view, and had never seen ill effects.

In closing the discussion Dr. Hare explained that he did not dispute the value of hydrotherapy in typhoid fever, but deprecated routine treatment of any kind. It may not be amiss to add that, in private conversation, Dr. Hare referring to his own experience with the cold bath, stated that he dreaded

them more than he could describe and that in the whole course of his disease he could only summon up resolution enough to take three. He also remarked that even if he knew that the cold bath would improve his chances of recovery 25 per cent. he would refuse to take them except out of regard for and a strong sense of duty to his wife and children. His own personal experience with the treatment as administered at one of the best city hospitals had inspired him with such a physical antipathy and dread to the cold bath that he could never prescribe it as a routine measure and would only use it where it was imperatively demanded. He did not regard it as a finality in the treatment of typhoid fever and hoped in the course of a few years to see a more humane and less disturbing method take its place in the estimation of the profession.

At the same meeting, Dr. Thomas H. Dunn of Westchester reported a case of "Parasitic Chyluria" occurring in an adult woman, who had always lived in Pennsylvania. For several years she had been subject to headache with gastro-intestinal disturbance and suppression of urine, the attacks lasting about two days. Following this she passed milk colored urine, which not only contained albumin, red and white blood cells and fat, but also many active organisms, which were found to be embryonic *filarie sanguinis hominis*. This case, according to Dr. Osler, was the first of which he had any knowledge, in which the disease was undoubtedly contracted in the North. Dr. F. P. Henry had exhibited specimens before the College in 1896, of living filaria in blood taken from a colored woman, 29 years of age, who was formerly a resident of Florida, where it was believed she contracted the disease.

THE BOARD OF HEALTH of Philadelphia in opposition to the sentiment in the profession which led to the appointment of a committee some weeks ago, to confer with the Board and attempt to secure some modification of the rules requiring the placarding of private houses for cases of infectious disease, has issued the following circular:

WHEREAS, The members of the Board of Health of Philadelphia are unanimously of the opinion that the strict enforcement of Section 2 of the "Act to provide for the more effectual protection of the public health," approved June 18, 1895, is absolutely necessary to prevent the spread of disease, and

Resolved, That hereafter, without exception, all cases of cholera, smallpox (variola or varioloid), scarlet fever, typhus fever, yellow fever, relapsing fever, diphtheria, diphtheric croup, membranous croup, or leprosy shall be placarded. This is to be done by placing a placard at the most conspicuous point of every entrance of the affected premises. Should the medical inspector be in doubt as to what is the "most conspicuous point," or as to the necessity of further placarding, isolation or quarantine, he shall at once communicate with the chief medical inspector and follow his instructions.

All reports of the placarding of houses shall be made in duplicate, a copy of which shall be forwarded to the superintendent of police, who is requested to have them referred to the respective police districts, and the lieutenant instructed to report to the superintendent all cases in which the placard is removed. Such reports to be returned forthwith to the bureau of health.

When it is reported at the office of the chief medical inspector that the placard may be removed, he shall notify the superintendent of police in the same way he used to notify him of the original placarding.

THE POLYCLINIC HOSPITAL free lectures on popular medical subjects which were delivered by the Faculty last spring, met with such favorable reception that a similar course has been arranged for the present Lenten season. The dates and subjects are appointed as follows, all lectures being given at 5 P.M.: March 4, The Filtration of the Water-supply of Philadelphia, by Henry Leffmann; March 9, The Prevention of, and Nursing in Typhoid Fever, by Augustus A. Eshner; March 11, The Hygiene of the Infant, by Edward P. Davis; March 16, The Care of the Eyes and the Influence of Defective Vision upon Mental and Physical Growth, by Samuel D. Risley; March 18, Surgical Emergencies, by Lewis W. Steinbach; March 23, The Essentials of Health, by Judson Daland; March 25, Hypnotism and Allied States, by William G. Spiller; March 30, The Cultivation of the Voice, by G. Hudson Makuen.

CHANGE OF ADDRESS.

Ammerman, U. S., from Keokuk, Ia. to Harbinc, Neb.
Bardon, F., from Keokuk, Ia. to 621 Monroe St., Quincy, Ill.
Back, A. J., from Keokuk, Ia. to Montpelier, Ohio.
Buzarg, I. S., from Keokuk, Ia. to Belinda, Ia.
Booth, F. H., from 357 W. North Ave. to 662 Cortez St., Chicago, Ill.
Brenholtz, W. S., from Columbia to 36 E. Walnut St., Lancaster, Pa.
Beardles, E. St. Clair, from Water Valley, Miss., to San Diego, Cal.
Friswell, S., from 18 School St. to 181 State St., Springfield, Mass.
Friedel, M. J., from 468 Grand Ave. to 1228 Milwaukee Ave., Chicago, Ill.
Garvin, W. C., from Millington to Vassar, Mich.

Ghrist, D. M., from Keokuk to Pella, Ia.
Hart, H. H., from 114 Powell to 2325 Bush St., San Francisco, Cal.
Jackson, G. E., from Wheaton to 252 Nicollet Ave., Minneapolis, Minn.
Luburg, J. N., from Keokuk, Ia. to Stafford, Ohio.
Layton, C. S., from Durand to Delray, Mich.
Morton, E. E., from Keokuk to Vincent, Ia.
Mitchell, A. H., from Deer Lodge to Warm Springs, Mont.
Noren, G. P., from Keokuk, Ia. to Geneseo, Ill.
Reed, W. H., from Keokuk to Perry, Ia.
Russell, C. R., from Keokuk to Ottumwa, Ia.
Rectanus, F., from Cincinnati, Ohio, to cor. Preston and Market Sts., Louisville, Ky.
Shollenberger, C. F., from 2162 Larimer St. to 2309 Larimer St., Denver, Colo.
Thomas, C. H., from Dansville, N. Y. to 1633 Locust St., Philadelphia, Pa.
Van Slyke, W. H., from Detroit to Tamarack Mine Hospital, Calumet, Mich.
Whiting, E. D., from Alma, Mich. to Presbyterian Hospt., Chicago, Ill.

THE PUBLIC SERVICE.

Army Changes. Official List of Changes in the Stations and duties of officers serving in the Medical Department, U. S. Army, from March 5 to 11, 1898.

Capt. Norton Strong, Asst. Surgeon, is granted leave of absence for six months on surgeon's certificate of disability, to take effect upon the expiration of the ordinary leave of absence granted him.
First Lieut. Thomas S. Bratton, Asst. Surgeon, upon the arrival at Ft. Niobrara, Neb., of First Lieut. Brainard S. Hingley, Jr., Asst. Surgeon, will be relieved from duty at that post and ordered to Ft. Leavenworth, Kan., for duty.

The following named medical officers are relieved from duty at the Army Medical School in Washington, D. C., to take effect upon completion of the course at the school ending April 1, 1898, and ordered to take station as follows: First Lieut. Henry Page, Asst. Surgeon, Presidio of San Francisco, Cal.; First Lieut. Bailey K. Ashford, Asst. Surgeon, Ft. Sam Houston, Texas; First Lieut. Henry A. Webster, Asst. Surgeon, Ft. Reno, Oklahoma Ter.; First Lieut. Jere B. Clayton, Asst. Surgeon, Ft. Clark, Texas; First Lieut. Brainard S. Hingley, Jr., Asst. Surgeon, Ft. Niobrara, Neb.; First Lieut. George Rauehuss, Asst. Surgeon, Ft. Apache, Ariz.

A board of medical officers to consist of: Col. Dallas Bache, Asst. Surgeon-General; Major Walter Reed, Surgeon; Major James C. Merrill, Surgeon; Capt. William H. Arthur, Asst. Surgeon; First Lieut. Alexander N. Stark, Asst. Surgeon, is constituted to meet at the Army Medical Museum Building in Washington, D. C., on Monday, May 2, 1898, at 10 o'clock A.M., for the examination of candidates for admission to the medical corps of the Army.

The Journal of the American Medical Association

VOL. XXX.

CHICAGO, ILLINOIS, MARCH 26, 1898.

No. 13.

ADDRESS.

EVIDENCES OF THE PROGRESS OF NEUROLOGY AND MEDICAL JURISPRUDENCE.

Address of the Chairman, Presented to the Section on Neurology and Medical Jurisprudence, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY WILLIAM J. HERDMAN, M.D., LL.D.

ANN ARBOR, MICH.

In compliance with the by-law of this ASSOCIATION, which specifies the subject upon which the Chairman of each Section shall address its members, it becomes my pleasant privilege as well as duty to attempt a brief review of the progress made in neurology and medical jurisprudence during the past twelve months, and to hazard a few suggestions as to the conduct of the future work of the Section, which if they shall be adopted would, in my judgment, greatly improve the efficiency of its function.

And here it might be well to call to mind what the function of this Section is, and what we, who constitute its membership and attend its sessions from year to year, are attempting to accomplish.

No doubt the motives which influence us to attend these meetings annually are many and various. Social, fraternal, recreative, and perhaps at times even less laudable inducements than these call us together and cause us to seek fellowship with those whose paths of labor and experience are similar to our own, though found in fields far separated. But underneath these lighter and more transient motives for our assembling, will be found the imperative incentive of the love of truth, and the desire possessed by every earnest soul to seek it for its own sake and to promulgate it.

No bond less vital than this could have for fifty years maintained, in ever-increasing strength of membership and influence, this National ASSOCIATION, or have brought about the orderly segregation of it into the natural groups of Sections which have gradually evolved from it, like the members of one body fitly joined together, separate in function yet interdependent, essential each to all. It is the search after truth that has created this ASSOCIATION, and a more intimate and we trust more efficient search that has determined these differentiations.

The Section which we represent is one of the later developments, but its formation was a natural separation in the interests of greater precision in the search after the normal and abnormal phenomena of the nervous system, and in the attempt to know what is, and what ought to be, the law governing the courts in cases where medical questions are involved.

If, then, the *raison d'être* of this Section in common with others of this ASSOCIATION, is that, by means of it, the pursuit of truth in the fields which its title

covers may be made more effective, we, its members, should see to it that this purpose be not lost sight of, but be made the primary motive in all of our contributions and discussions. We will learn from one who is well qualified to perform the task, how well the members of this Section have discharged this function hitherto, and we trust that the honorable record of the past will stimulate us to even greater zeal, and to the adoption of even more efficient methods for the future.

Months and years do not serve as mile-stones to mark the progress of human knowledge, or measure the evolution of discoveries or ideas. In an attempt to portray the advance made by the mind of man in mastering and comprehending the intricate play of energies in the midst of which it is placed and of which, in some sense, it is a part, we must depart from the imagery of the conquering army, moving on from victory to victory, where the date of each can be forever fixed in the time calendar of events, and adopt, instead, the figure of the growing plant, where the selective assimilation of the developing germ exhibits notable increase and elaboration, from seed to perfected flower or fruit, and yet when the eye is directed to a single day of that increasing growth, it might not discover any marked advance beyond the progress of the preceding day.

The growth of knowledge, like the growth of plants, may be ever active, and at no time can it be said with truth, that this or that stage of the growth is less important than another in attaining the ultimate perfection, and yet, to both the interested and casual observer, these stages may differ in interest and attractiveness, according as they reveal by their suggestiveness a less or greater glimpse of the broader truths that lie beyond, or open up more clearly the paths that give promise of leading to them.

These premises seem called for in view of the fact that in the twelve months that have gone by since last we met, the growth of neurology has not been signalized by any unusual outburst of fruitage or efflorescence. Yet they have been busy months for all who are actively engaged in any division of the broad field of neurology.

We can safely say that the work that has been accomplished in that time is superior, both in quantity and quality, to that done in any previous period of equal length in the world's history, and yet we are unable to refer to it as an epoch-making year in the progress of neurology, for it has not been marked by any notable discoveries either in the science or the art. Each worker has been busy digesting and assimilating the discoveries of previous years, and adding his mite of observation and fact to the store of knowledge already accumulated.

But when we recall that never before today have there been so many thoroughly educated and energetic physicians devoting their time exclusively, or for the

most part, to the study of disorders of the nervous system, and are reminded that never have the resources of associated fields of research been so replete with helpful fact and suggestion, we can rest assured that, whether it is each moment apparent or not, the amount of actual advancement made in a year's time now is greater than was possible in any previous year.

But if we can not mark off the boundaries of the year that is just past so as to include within them many notable achievements to the credit of neurology, we can at least point to certain evidences that the growth is steadily enlarging, and is preparing for expansion into wider fields and greater usefulness. This is made evident by the capacity it has recently exhibited in the discovery and assimilation of new facts in the histology of the central nervous system.

Even though these discoveries have already to some extent, and may still further, require a reconstruction of the framework of our neural physiology, and consequently of our theories of the pathology of many diseases, and though our established modes of practice will likewise need to be modified in some respects to adjust them to the new conceptions of the neuron, yet the vitality of the plant is in no respect endangered, but rather quickened and strengthened by such radical changes in pabulum.

While we would all be disposed to smile at the absurdity of an attempt on the part of any one to deny, in the face of unmistakable demonstration, the revelations in cell structure and arrangement which the improved methods of staining and manipulation have made, yet it is a commendable conservatism that will not at once renounce old and well established theories, upon the announcement of some facts that appear at first glance to be antagonistic to them.

It is, on the other hand, equally commendable and a sign of healthful activity when a revolutionizing order of facts can be injected into a developing system of knowledge with no other effect than that of healthful stimulation of the normal processes to greater energy. The recent advances in cytology seem to have had none other than just such quickening effect upon all branches of neurologic research. Progress in neural physiology and pathology must of necessity follow closely on the advance made in more exact knowledge as to the structure and arrangement of the nerve cell, and it now appears clear that within the walls of this minute laboratory—the nerve cell and its prolongations—our attention for some time to come is likely to be arrested and fixed, for to it as the primary theater of all the activities of the nervous system, normal and abnormal, we have at last been led in the ardor of our search for the causes of the protean forms of nervous diseases and by our anxious desire to prevent them and to relieve the sufferers.

Again we may point with confidence to the recent accessions to our special literature as another substantial evidence of healthy growth in the science and art of neurology.

First assimilation, then construction, and finally secretion represents the natural sequence of organic processes. We have already so far matured that we have begun to give back to the world in permanent form some of the fruits of our researches and investigations. Quite a harvest in neurologic book-making has been garnered during recent years, and not a few of the best products have appeared during the last few months, and in this our American soil has been

most fruitful and adds much to our credit for its excellence, unsurpassed as it is by that of any other country, even though there has been no famine elsewhere. The activity that has been shown by American authors recently in putting forth so many excellent text-books and monographs treating of nervous disorders, gives assurance that this branch of study will henceforth receive its appropriate share of attention in every well-devised medical curriculum, and that those already in the field of practice have now every facility for fully informing themselves as to the latest acquisition in this class of disorders. While the great bulk of that which has so far been published by American authors, and is original with them, treats mainly of the clinical aspects of neurologic questions, yet there are encouraging signs that it will not be many years before this country will be the leader in special research work in neural anatomy, histology, experimental physiology and pathology, as well as in the clinical study of the phenomena of the nervous system. For many years the experimental work in neurologic fields by American physiologists has received international recognition by reason of its value, and now in a dozen or more educational centers in this country laboratories have been established for special research work in neural pathology, which give promise of soon surpassing in their facilities for investigation, anything that the specialists of Europe have ever dreamed of. I need only call your attention to the comprehensive plan outlined by the Director of the Pathological Institute recently established by the Commission of Lunacy of the State of New York, and published in the bulletin of the State Hospitals of that State, to convince you that American neurologists have no narrow conception of the work which lies before them, nor any hesitancy in rightly undertaking to do it when the opportunity is offered and the facilities furnished.

From laboratories such as these we have a right to expect that our literature will soon be enriched with the products of well-planned research, which will materially aid us in clearing up the etiology and pathology of many nervous disorders which now baffle the skill of the clinician.

The universal interest and activity in compiling and promulgating neurologic knowledge has brought prominently into view the need of greater uniformity in the neural terms, especially with respect to those used to designate the various parts and locations in the central nervous system.

Science knows no national boundaries and the advance demands that provincialism in terminology give place to more cosmopolitan terms and that a language be adopted the significance of which would be the same wherever uttered. To this commendable purpose a well known American anatomist has devoted much time and scholarly ability for many years, and we are glad to see that at last his labors are claiming something of the favorable recognition they so richly deserve, and that the American Association of leading neurologists, together with the American Association for the Advancement of Science, and the Association of American Anatomists have formally stamped with their approval a certain number of terms, and have recommended that they be employed in preference to their less appropriate synonyms. The step is in the direction of clearer and more exact description, and will do much to rid our technical language of obscurity and confusion.

It would not be out of place, but rather an opportune and helpful act, for the members of this Section to add their support, by vote or resolution, to this effort at uniformity and so declare themselves for greater simplicity and scientific accuracy in the expression of thought upon subjects of special interest to us.

But it appears to me that in no way has neurology exhibited its vitality and progress in recent years to greater advantage than in the relationship it has shown itself to bear to those sciences of an altruistic type, which are the peculiar products of modern times.

In the beginnings of any independent line of research among phenomena possessing an importance sufficient to form a distinct department of knowledge, such as this of ours, there must of necessity be first a period for collecting data; an accumulation of facts with apparently little in common, except that they relate in some way to the field that has been chosen for separate consideration. The natural tendency during this primitive period is for the mind of the observer to be occupied with distinctions and differences rather than with resemblances.

In the beginnings of neurology cases of nervous disorders and the features that characterize them must needs first occupy the attention. The records of individual instances of disease presenting different phases must accumulate until, through repetition and comparison, a type is discovered and accepted for each form of disorder which deserves a separate place in the nomenclature.

This may be said to have been the period for neurology in which it was engaged in establishing its right to independent existence; when it was occupied with marking out the boundaries of territory peculiarly its own. This pioneer work is now well done, and may be said to be complete. Our right to separate existence has been established and recognized, and our growth as a sturdy branch of medical knowledge has already borne rich fruit. But while engaged in this close analysis of the phenomena of disease in the realm of the nervous system, we have had frequent occasion to note that much that we have come upon has a value beyond the limits of our special field. While searching for truth with the view of making use of it within our limited sphere, we discover that its rays extend far beyond our little world and illumine spaces upward, and beyond anything which the mind of man had hitherto attained.

The community of knowledge and of truth and the relationship of a part to the whole, is made evident by these researches, furnishing material aid to co-workers in other fields, which at one time were thought to have but little in common with our own. It is one of the most gratifying evidences of the growth in neurology that investigations in this field, are daily proving more and more helpful in solving the problems of anthropology, education, psychology, criminology and sociology.

Each one of these departments of what may be termed the humane sciences may be said to have had its origin in discoveries in neurology.

They are at least experiencing the transforming influence of discoveries first made in our special field, and we are justified in claiming for ourselves priority in the beneficent work which these associate sciences are, in their practical results, accomplishing in the better conduct of our schools, asylums, reformatories

and prisons, and in the more rational attitude of the public mind toward the defective and dependent classes of our fellow men.

It is with considerable diffidence that I venture to say a word regarding the present tendencies of medical jurisprudence, since neither my opportunities nor my training have prepared me for utterances on this subject that are worthy of much consideration. Indeed I have, in common with other members of this Section, questioned the propriety of our assuming to compass within the boundaries of our limited membership the entire range of topics that are grouped along the borderland where law and medicine unite. It is true that a very large and most important share of the problems which demand the attention of the physician and lawyer jointly arise within the boundaries of neurology, and it may have been wise at the outset to have appended the department to this Section, rather than to that of any other now existing.

But since there is not a Section of the Association whose members are not at times directly interested in the legal aspects of questions which of necessity arise in connection with their special line of work, and since in one Section especially (that of State Medicine) the legal relationship of the physician to the laity has been greatly enlarged within recent years, and is destined to become still more so in the future, it has seemed to me that the time is near at hand when the establishment of a distinct Section of Medical Jurisprudence is advisable. As it is now, seldom are papers, presenting the legal aspects of medical subjects, offered to this Section unless they relate directly to perverted action of the mind, the brain, or nervous system in some other part, and even many of these have been of too general interest to receive from the members of this Section alone fitting consideration and discussion. It would appear, then, that the time is at hand for the creation of a separate Section to be devoted in its work wholly to legal medicine. The field is already broad enough, and is every day enlarging.

To one not very familiar with the recent literature of medical jurisprudence, and yet who has attempted to make a cursory review of what has been presented on this subject in the law and medical journals during the past twelve months, it appears that in this line of work the courts have been chiefly occupied with cases of suspected poisoning, where medical questions involved have been as to the nature and actions of poisons, and methods of detecting them in the tissues of the body, either before or after death. These have been mainly questions of fact, calling for the testimony of the expert physiologic chemist and toxicologist, and in them no very broad principles of law or medical practice have been involved. There have been a few instances of another class of cases, however, in which a certain very important principle is involved, which appears to me worthy of being brought to your attention, as they furnish food for very careful reflection. The more so as the same principle, of the sacredness of the absolute rights of the individual, has been threatened by proposed enactments in several of our States during present and recent sessions of their legislatures. The citation of one case commented on in the March number of the editorial column of *The Green Bag*, will serve to bring this principle before you. I will quote this comment in full:

"A very novel case regarding the right of a surgeon to go beyond his specific authority in performing an operation was recently tried in London. Miss Beatty, a hospital nurse, submitted herself to Mr. Cullingworth, an eminent surgeon of London, for an operation of ovariectomy. It was admitted by the defendant that she forbade him to go beyond the single operation, but he testified that he refused to perform the operation under that condition and told her she must submit to his discretion. This she denied. Finding it necessary, in his opinion, to perform the double operation to prolong her life, he did so. He testified that in view of the patient's wish he had hesitated, but he concluded to overrule her objection. In consequence she felt compelled by conscientious scruples to break off her marriage engagement. The most eminent surgeons testified that they would refuse to operate under such a restriction. Sir Thomas Wells, however, the greatest expert, testified that he thought the double operation in this case was unnecessary, but he had no doubt the defendant acted conscientiously. The defendant and his assistant testified that the plaintiff would not have lived ten years without the double operation." There was a verdict for the defendant. This of course may have been based on a finding that the defendant had refused to submit to the condition, and that consequently the plaintiff had tacitly assented. If any inference is to be drawn from the case that a surgeon may exceed his specific instructions, not dissented from by him, even if he deems it necessary to prolong or save life, it is bad law. Miss Beatty had a perfect right to prefer to live for ten years, and to be for that time a wife and possibly a mother, rather than to live the ordinary length of time unmarried, or be a barren wife. The matter is probably less serious to the female sex than a somewhat analogous operation would be to the male, but we believe that it would be rather difficult to induce a judge and a jury to justify a surgeon in disregarding explicit instructions of a similar purport on the part of a man. If a second operation, in the case under consideration, should have proved necessary, it would have been easy to make it, and not unsex the sufferer at the outset. We confess that we are surprised at the verdict, and that in any view we regard the result as wrong. We have sympathy for a woman who demands that her sexual physiology be respected, despite the custom of surgeons. We fully agree with the *New York Law Journal* that, "Where a proposed operation is as clearly the subject of definite agreement as the one under consideration, and especially where the worst that could result from following the patient's directions would be the necessity of submitting to a second operation later, we think such directions should be accepted as morally binding upon the surgeon, and held legally controlling by the courts."

This case serves for a type of many, and the principle involved, is the sacredness of what Blackstone defines as the absolute right of the patient which no physician or surgeon may presume to invade at his own discretion, assuming to decide what is best for the patient without the latter's full acquiescence in that decision.

In the proposed legislative enactments above referred to, and which have been brought forward in so many different localities as to indicate a general tendency in this direction, the attempt is made to check the current of crime and misery at its fountain head

by unsexing the inmates of institutions for epileptic and feeble-minded, and the inmates of prisons and houses of correction who have for the third time been convicted of crime.

The difference in principles involved, between such proposed legislation and in the special case just cited is, that in the latter case the surgeon assumes to violate the absolute right of the person of the patient in what he believes to be the patient's interest, whereas, in the former, society, by legislative enactment, undertakes to invade the absolute rights of the individual on the assumption that it is for society's own interest to do so.

This assumption on the part of society of the right to protect itself against possible future harm by encroaching upon ground that in the fundamental principle of law is regarded as sacred to individual rights, has found its champions and defenders among those high in authority in both medical and legal circles and this has opened up a field for medico-legal warfare upon which the contest will soon be raging. You can well see, without our attempting to discuss the various phases of this question at this time, that it is one worthy of our most serious consideration and concerning which it will be well for us to be forming an opinion.

The broad question as to how far society is justified in attempting to protect itself against remote and possible harm by provisions which curtail the inalienable rights of the individual, is one which to be rightly answered calls for the widest knowledge and the wisest judgments which the human mind can attain. It is even a question as to whether the solution of such questions as this will ever be rightly solved within the domain of civil law.

I will now venture to call your attention to a few features in the organization and management of this Section which seem to me to be in need of decided change if the work of the Section is to become a positive factor in the advancement of neurology.

Primarily the membership of this Section is too evanescent as yet to be relied upon for the prosecution of any persistent and settled purpose.

The various Sections of the AMERICAN ASSOCIATION should each be the culture field of the best thought, the most mature products of the human mind and skill in that division of medical work with which it assumes to deal.

The first requisite to this result is that the membership of each Section be made up of those who are interested and able in that particular branch of medical science above all others, and that they identify themselves with the work of the Section year after year.

This is not now the case. I do not know how it is with the other Sections of this ASSOCIATION, but this section has not at present any permanent membership upon which its officers can rely for support or assistance, in attempts to further the work of the Section. There is not even a list of members. Not the shadow of an obligation exists on the part of any member of the AMERICAN MEDICAL ASSOCIATION, as far as any tangible promise is concerned, to devote his efforts in the main to the interests of this Section.

You can very well see that this is a very insecure foundation upon which to construct a fabric of any permanency or value, and the marvel is that with such a loose organization this Section has been able to accomplish as much as it already has.

Steps should at once be taken to effect a more permanent organization. The membership of the general ASSOCIATION should be canvassed by the permanent secretary, by special committee, or by the council of this Section, and those members who wish to devote the whole or a share of their time to the work of this Section, be asked to declare themselves so that they may be counted upon hereafter to contribute to the work of this Section either in individual or associate papers or discussions. I personally very much doubt if this result can be brought about to the satisfaction of those interested in the permanent growth of this Section without making the secretaryship a permanent office, so that through his efforts the valuable experiences and products of successive years be preserved.

By such a change as this—a permanent secretaryship—our Section will begin to take on a vertebrate existence, but without one, at least, of such centers of ossification our undifferentiated, ameboid membership is likely to continue. I am aware that this suggestion, if thought worthy of adoption by you, will require a change of organization which transcends the powers of this Section, but in the interests of more efficient work we should not hesitate to ask that the power to effect such change be granted.

When once a fixed, rather than a floating membership, is secured, it will then be possible for the officers and council of the Section to institute changes in the method of preparing for the annual meetings that will make them much more effective.

If this Section is to fulfil its mission in bringing together the men and the conditions by which the science of neurology and medical jurisprudence are to be advanced, and if it is to serve, as it should, as the channel through which the latest and most enlightened conclusions in these special fields are to reach the great body of physicians, and so the laity, throughout this broad land, then such measures must be adopted as will keep the work of the Section at each meeting up to the requirements of the times, and prevent the wasting of valuable time and opportunity with trivial, trite, or inconsequent matter.

The main topics for consideration and discussion for each meeting should be determined upon many months in advance, and every care should be taken to have them fully presented. With a permanent secretary our official board would be well constituted to enable us to follow out a consistent plan and purpose in this regard, and our meetings could then be made the source from which the final and most authoritative word would be heard on the live topics of the day in our special departments of medical science and practice.

Into this Section of our ASSOCIATION should be brought the representatives of the various departments which are contributing to the advancement of those branches of knowledge which we are attempting to foster. The most learned anatomists and biologists, the ablest pathologists and physiologic chemists, the most experienced alienists and neurologists, and the wisest jurists which this great nation can furnish, are needed here to fitly deal with the problems which are continually before us for consideration. And where more suitably than in this special Section of our AMERICAN ASSOCIATION, representing as it does all departments of medical activity on this continent, could all these elements combine with greater expectation of evolving well rounded truth? It is my opin-

ion that only in an association of this character, composed of a membership representing all phases of the body-medical, are the conditions fully secured for eliciting the broadest and clearest conceptions of the origin and natural history of disease, the tendencies that lead to it, and the measures needful to combat it.

With such an organization and such a membership as here suggested, this Section would be capable of advancing in its proper sphere of work purposely and consciously, and in the direction of humanity's greatest needs. We would then, by co-operative and predetermined action, be able to concentrate our thought and attention on the settlement of questions with respect to the etiology of certain diseases which now affect the highest functions of the nervous system.

It must be apparent to all, that as the future progress of mankind is of necessity along the lines of intellectual, moral, and spiritual attainments by the individual, and that such progress is possible only as the lower powers of our nature become subject to the higher and that, since these higher powers, as we are now constituted, reside in and have their expression and depend for their growth and development upon the activities of the nervous system, the most important problems involving human destiny are laid at the feet of the members of this Section for solution. Do we appreciate this? Do we recognize that it is from just such associations as this that mankind must receive the authoritative word declaring that the researches of science have completed the circle of the universe, and that she has clasped hands with revelation and joined with it in the utterance that intemperance, lust, licentiousness, self-seeking are degrading and debasing, blasting and dwarfing man's higher capacities for attainment, since they directly operate to the injury of his nervous organism, sapping its energies, and cramping its expanding powers: while on the contrary, temperance, purity, peace, and a continent life and conduct are evidence of a well balanced organism, and is in harmony with all law, human and divine.

These are, perhaps, far reaching conceptions of the growth which it is possible for us to attain. But I do not doubt that you concur with me in the opinion that this is the line of destiny and so of duty for neurology, and if so why waste time on less inspiring ideals and narrower conceptions of our function?

THE GROWTH OF COMMERCIALISM IN MEDICINE.

Read before the New York State Medical Association, Oct. 12, 1897.

BY JOHN SHRADY, M.D.

NEW YORK, N. Y.

In approaching this complex theme there are many besetments which involve more or less controversy. Indeed, there may be suspicions of ulterior motives for, mayhap, an untried form of ambush, since it is widely conceded that statecraft may even masquerade as diplomacy. At the outset, however, there need be a disclaimer to the effect that there is to be any eulogy of honesty in any form, lest it be set down as cant in favor of the code. The purpose, then, to be announced is that of self-examination as to whether or not there may not be some sins of our own which require the penitential tear.

We have heard not a little of the outrages that have been perpetrated against us in the way of non-recognition, or what hurts our pride not a little, of that indefi-

nite something which we consent to call ingratitude. It is not to be gainsaid that self-esteem has been sorely wounded and that we have been balked in our efforts to hoard up the Klondike surface washings amid unesthetic surroundings of that barbaric simplicity which makes the want of probity fatal. That there have been hardships of no mean sort, the best panoplied of us stoutly maintain, for did not this very Borough of Manhattan begin the history of our profession with a petition for the monopoly of shaving?

But in those days of unusual sanitary conditions, when the ocean breezes did not sough against cloud-piercing towers, nor even whirl around the massive chair of a De Peyster in Bowling Green, there was little heed given to aught but pastoral joys or nocturnal frolics. There were then no heavy licenses for the sale of very small wares, and the little learning in vogue was easy of capture without question of its source. In very truth, the local color had then a sober tint and the picture a deep perspective. Since then, posterity has garnered the honest fruitage of not over-much labor, and has whet its appetite with the spiced offerings of the luxurious voluptuaries from every clime beneath the sun. But those halcyon days are gone, for the home of commerce has come where once were quaint cottages and low-bending trees. The counting-house has crowded away the May-pole, craft has displaced honesty, and the agent with his satchel of samples crosses the threshold with the ambling grace of Mephistopheles.

Now the schoolboy chuckles over his barter, for has he not early learned the power of wealth, and that money is current everywhere no matter how obtained! He has mastered business long before his prayers, and knows the biography of every merchant prince. How much, and how readily, is about his only ritual! If money comes not quickly what time can there be left to him for the wild carnival, which scatters what it can not use. Thus, with a starving soul he goes to the banquet of life. Gold, gold, but never the idolatry of the great, the unselfish and the true, is his prospective award. He bites the rosy apple but to fill his mouth with ashes. Aye, he is to be denied what he has won from the unsuspecting, for the irony of fate has long ago taught him that the calm of philosophy is not the accompaniment of the pride of possession. Still he ever searches for new fields, sterilized by auriferous deposits. Grown to manhood with the empty shout of public weal, he saps the foundations of public morals. But what boots it, he hugs his gatherings from which the eyes of angels are averted, and deludes himself into the belief that his conscience-smitten gift is charity. Now of this name, or *umbra nominis*, we have heard much. Business men claim to practice it with the click of machinery and vaunt it even in their supplications, while they wince at the voice of the whining beggar who plies his art upon their credulity with the saddest eyes. They keep a syndicate and the forms need no revision, for they have been passed upon by their board of managers, who investigate but seldom find their standard of poverty. What shall we say, is it high or low? With such seeming virtues romance endows the rosy-cheeked milkmaid, and to it the rollicking tourist scatters his coin. But here, in this boasted metropolis, the cajoler of the best traits of a common humanity skulks away with his rags and tatters from off the face of the cleanest streets. His picturesque outfit and beseeching face no longer linger to be

beckoned into a studio as the model of a grand old Lazarus. Duty, the synonym of all that is obnoxious, is limited to the nickel-in-the-slot and the almoner is invisible. Faith is Charity—the sisters have the confusion of twins.

To this, we add without sarcasm, that we have no need to question the wisdom of business men, who have caught up with the nineteenth century in the rant of its worship. Is poverty, then, a sham only to be mitigated when abject? Is it never to be led by the gentle hand? Must starvation never be relieved except behind the poor-house door? Say not rather that charity ceases when regretted, and that the personal equation vanishes when there is too much organization. Justice at a lynching bee likewise is but a mockery when diffused through many hands gripping a long rope. Like the still remembered cartoon, thumbs point to the culprit with a "t'was him" around an unbroken circle.

When we physicians of the long ago, for the years flow swiftly, were wont to say but little of fees and chanced with the future for a livelihood, was there less recompense than now? Was there not more gratitude and more tender remembrance than in this age of rampant misgiving and shocked responsibilities? Did then the poor talk of our experiments or vivisections? Did we then chase the coin down to its covert? Rather did not the turmoils of conscience make us penitent and tender? Did we not point to the tribunal somewhere, only too glad that the deception was not ours and that we had missed the sickening potion of discovery? Did we then care to cast the sinless stone? Did not our humility grow with our years, for was there not before us a shore bordering the misty sea of all knowledge?

Someone has defined charity to be the telling of A to B what C ought to give. This is undoubtedly the commercial custom. As professional men we have always been more practical with what few virtues we are supposed to possess. We scarcely protest with the hand outside of the pocket. Think all guilty until proven innocent, has never been our motto. In truth, have we ever been on the alert for "the little heaven below" which cash-in-hand is supposed to give? Knowing that we have more rights than we ever cared to claim, we have waived them for the sake of a swifter progress. We have turned from our ledgers to our books, from our regrets to our cases. Why should we bandy words with a chattering crowd, or carry our right of petition up to a legislative hall? Who cares for our woes, for have we not always been too proud to parade them? In the present drift toward paternalism we might even say with Emerson, we are only "bartering subsidies for privileges." Know you not that there was long a scribbled inscription in one of the rooms of Temple Bar, London. "Law is dear, but it is prime, it is prime." The price is high and the commodity invisible. The year between us and Santa Claus has ever been exceeding long and the gifts contemptible. But then does the long-shoreman get any more for the dripping body that he has fought to the dock? Does our lawyer friend ever forget to note an interview?

Let us indulge in a little introspection. Let us see if we have not ourselves fallen away from our high standards. Let us admit that we have adopted some of the formulas of trade, for what else can we say when such advice as, "You must make your market," is baldly flaunted with never a zest of Machiavelli, that all governments are liars. Let us refer to

that other almost criminal insinuation, "Well, there are more ways than one," which is, oh, so well hammered into our ribs. Our love of greed has been stimulated by the rarity of exceptions, and a vendetta has been established for mutual extermination. There has been rife a persistent effort for undivided possession, for a kingdom without satraps, for a dogmatic isolation conjoined with a shameless effrontery. Covert arts have been in vogue to cut off the opportunities of the honest plodder, who is assigned the rôle of the unskilled workman for the chance of a minimum reward, while stupendous fees are deemed attainable by the merest clutching. All these, not with design, we admit, but still the consequences are not a whit less deplorable—aye, to the verge of abject degradation. But the great public has been enlightened by the usual slipshod methods, to-wit, with information on just enough to alarm their fears. To be sure, there has been no flagrant offense offered to the most exquisite taste, none of the nimble art of the street preacher balancing as wares the coarsest virtues on his finger tips, but still the suggestions are dire and exact. The rattle and clatter of the plates only tell of old tests and old escapes.

The journalist may have trimmed from the common heap, the jewel of modest merit, but the gravity of our doubts is most oppressive. His zeal for the public may have been of the "purest ray serene," but unfortunately there are many judgments at variance. He has his friends, too, who stoutly defend him against the charges of purloining microscopic slides, portraiture and photogravure misfits for newspaper columns. Still he is persistently correct in his minature, but somewhat obscure in his statements of superb excellences. This editor of ours so loves to revel in surprises, so well uses the power of the press, and pirouettes so trippingly away from the latest scandal to the worship of the latest paragon. Thus jocularly do some men their duty regardless of the woes of their victims. But seriously, we would excuse such blunders, were they not so fatal to budding reputations. Yet these catastrophies may befall the humblest Fellow of our Association, even him, 'who storms over being found "among the distinguished persons present" and who is so vexed at the absurd praise, oh, so lavishly bestowed.

What an outrage upon a physician who simply tries to do his duty, just as does every other brother of the profession who seeks not his own but another's welfare. If he elects to mitigate an eulogy by a declaration of his merit (alas, far below the average), he is incontinently accused of an attempt to prolong a controversy for the sake of notoriety, and not at all in the interest of a nobler standard in his own calling. He has laid his tribute before a shrine and is therefore roundly denounced for keeping a mascot. Should he be convinced of the virtues of a mineral water, his jealous brethren accuse him of merely stringing his hard-earned honors after his name! But he has really been duped by an advertising agent, who has played upon his credulity. His simple scientific disposition has been made to subserve the ends of an enterprising manufacturer, who is exploiting his discoveries throughout the land. Even those references "by permission" on the cards of struggling nurses may have been an abuse of the best of natures. Alas, such is the enterprise of trade! Such are the indiscretions of our blataut admirers who keep not within the bounds of their own affairs!

It is just by such methods as these that civilization is retarded by the only "still small voice" that our too trusting consciences are made to hear. We can never be brought to understand why it is that the merchant from behind his bargain counter keeps forever giving out his malicious opinion that no physician can be made over into a business man, why our modes are held to be crude, the language of his science, jargon; for says the advertising expert, where is the art of not saying, where the non-obviousness of the delicate insinuation that our commodities are just a mite superior to those of our rivals? Have we done more than our duty to the public? Where are our arts of faint praise of possibilities? Where the long vista of years yet to come, where the negative yet to be developed and where the well-graced actor yet to enter? Sweet plaudits such as these says our man of a commercial emporium, may be cheaply had just at the cost of a quizzical shrug or a tone of sadness; if not thus won, why not be content with the "reading notice," stumbled on unawares and thus cheap at any price? That neighbor of yours in yonder palace, who stands up grandly in his pew and essays to deceive with pious interjections, has fared in his day and generation much better, for the wails of his victims possess the soft cadence of a longer distance; aye, just the width of the gulf between Dives and the poor man in Abraham's bosom. Still in the seesaw of an inevitable destiny the one as ever looks down and the other up. The one has a scowl, the other a smile; for joy has fled from one, but abided with the other. But let us not therefore refrain, for after all retribution may be only a myth! Fall down and worship, the wealth of the valley is yours.

What says the State—the state of all nations, grades, forms and conditions, which but enforces fealty to itself and jeopardizes naught for its own interests. It is not strictly charitable, but it suavely does the work of charity, without heed of the hardships or perils of the person. Aye, along its moving armies there ever rings out the hoarse high-pitched order: "Wounded to the rear." If it helps it is without coddling and without the soothing stroking of kinship, only as a conglomerate mass it moves and flounders; like the leviathan buffeting the waves it is merely powerful for displacement. On its day of danger it may call for levies, but the pay it gives is the sense of duty and a tinsel crown of martyrdom. It may have a thrift of its own, but has made no provision for the legacy after death. It talks of ignorance and vice, but not at all of misfortune, for with it a blunder is worse than a crime. It may fight, but seldom arbitrates, and when revolution or carnage comes it dies washing its hands with a supercilious curl of the lips. The prating is for justice, swift, stern and sweeping, not for mitigating mercy, charity or any other persuasive grace. Like the street gamin, it is disappointed that the patrol wagon holds only thieves instead of murderers, for the former may work out the charity won by their enterprise while the latter would have been chief in some grand lurid drama, with defiant and mock-heroic faces. This gamin of ours but wants the sensation, the curdling little red rivulet. He, too, needs the carnage that leads to glory, but never the glow of the fireside that beckons on the slumber of peace. Why then should we mix our appeals with clamor for the royalty of a meagre patronage or a short official life? Let us rather be dumb before our shearers that our submission may pass for stoicism, our self-

conquest for grit. May we, too, not have honor for our scars?

That as a moiety of the community we have suffered in the financial depression of the past few years, none will have the temerity to deny. But acknowledgements are more or less painful. In a politico-economic sense, we have become versed in the maxims of supply and demand, we have heard much of over-production and have had many experiences of buying in the cheapest and selling in the dearest market. We have imbibed trades-union ideas, and have insisted on immediate and adequate recompense. We have catered to the prejudices of the dependent classes by informing them that our revenue was from the rich and that the surplus was cheerfully bestowed upon the unfortunate in lieu of fee-less skill. Why therefore should we complain if the much-talked-of gratitude was absorbed in the mere sense of a cancelled duty? If we referred our cases without demur to your hospital and dispensary, because our skill was far beyond the means of the applicant, why protest that damage came to our prestige? If we exalted the charity of our neighbor, why cavil if he received the credit? If we enhanced his reputation, why deprive him of the emoluments, be they what they may, if only such were the returns for his toil and trouble? Why not allow the wage we have scorned?

How few read the lesson of the right to give in the parable of the Prodigal, and how many waste their indignation upon him, who served his father, lo, these many years! The fault lies with a slinking away from our individual charities and a reference of what is our plain duty to a corporation or to the state itself. Both of which may relieve—be not startled by the harshness of the phrase—through motives of policy. In the squabbles of our childhood how soon we learned to conceal our grievances from our parents! How much more precious was the redress when the settlement was all our own! How much less the rancor when the skirmish was too brief to grow into a battle! How much happier when we had no grim judge to face whose regret was that the law provided insufficient punishment for the crime! Let us not, therefore, saddle our shortcomings upon those who bestow merely to escape importunity and appoint grand almoners because their sympathies are shocked at the mere sight of misery. Just so the brigands of old hoped to win eternal happiness by the pittance at the shrine. The self-tormenting saint, in his life-long practice of Samaritan virtues, erects a higher ideal and is much more sure of the hosannahs "to the good and faithful servant." What need, we ask, for that perpetual delegation of our very virtues along with our liberties to a hazy unification of a something we call power divorced from wrong? Is it any more distinct and select than the hug of the crowd?

As a profession, too, we have allowed ourselves to be deceived by over-statements of success on the part of those who have won the popular favor. We may even have enhanced our own merits by well-directed self-laudations, which in the young pass for enthusiasm; in the old for candor. While the merchant has speculated with capital we have sported with reputations. What have we gained; only an ownership insignificant and transient. Beginning a career when the votary of commerce is arranging for retirement, we find that our attainments do not advance us beyond the rank and file, whom we have been taught were created to furnish us with cases, to them incomprehen-

sible. Gathered up by the wayside and hurried into the institutions of learning, we have been taught the progressive glories of medicine, and especially that all of life was antisepsis. We have found that, after an awakening from our disillusion, our preparations have been mainly for a sham battle and that Jupiter, after dividing with the warrior and the merchant, allows the poet the whole world just because he has divorced it from its most desirable treasures. The ample room above, we have carried as a tradition, some of us from the kindergarten, and have striven as well to escape from the multitude, among whom statures are dwarfed and visions bereft of their tawdry mockeries. We soar, but soon strike the bars of the cage.

Somehow the self-deceptions of our commercial part do not beguile us, inasmuch as in our investigations we become annoyed, like John Hunter, by the quest after the guinea and envy the pipe and simple needs of some Virchow, poring over the deepest problems of life. To us in what should be the valley of content fit for a Rasselas, the luring invitation of the mountain top, upon which a castle may be built, has as ever withstood the flattery of our prayers. Let us not look upon legislation as a panacea or seek to abolish hospitals as a lesser remedy for our grievances. Let us not stultify ourselves by demolishing what for centuries we have been erecting. Much of our best work has been within hospital walls, and few would willingly part with the memories of our first "God bless you." We have been disappointed, it is true, but because of too much expectation and the absence of cringing appeals. How could we hope from the law but an extension of advantages and an enlargement of a community to which none of us can be admitted to full membership. How can we be exempted from competition by legal enactments! Still as we are expected no longer to pass upon questions, as jurors, we may become useful as signers of petitions and as a colleague expressed it, "practice medicine as a blind." We have not been the only ones who have worked outside of our proper spheres. Judicious investments rather than accumulated earnings are made by one of the English journals to explain the rather insignificant fortunes left by practitioners of more than national fame. With our diplomas we carried off the vows of the clergy, of whom we were once an integral part. We have always preached philanthropy, let us still defend the text and cease our strictures upon flaws in doctrine. Let us learn from the multitude how much may be done with a little.

Many are the arts of trade and often have we, as a profession, essayed to adopt them, but the glamor has not strictly deceived and our mimicry has been much too awkward. The intellect of the many headed we have already learned is by no means dull and the ways of the charlatan are soon divined. Our dignity is not of that order which prompts to stuff the bosom and to ride erect with a long curved sword for the homage of an hour. Why not, says our lawyer, the fee is large and a portion may buy a home? Somehow we have come to dread the "nevermore" of the croaking raven and even to belittle our services. The salesman of glib tongue, the financier of plastic conscience and the inventor of ready brain emerge from the mine far richer than we, whose competitors are too apt to be of our own household. Our pay is the bulky coin of the iron age, much too heavy for the convenience of commerce. Nay, further, it is our born prerogative

to serve our fellows, to defer their doom by kind offices and select none even for the value of their lives. The tradesman, the landlord and all who gain a livelihood out of the necessities of others, may flourish under the ægis of the law, but preferably not ourselves, for legislation knows but one remedy, that of a different and leveling method. It takes care to spread only on the thin slice. Much toil and much self-conquest is the screed of our book of fate. Let us read it with a contrite submission and like the beggar in the market place wait until the pittance grows into an investment.

It is not for us to waste life in banquet halls with well-rehearsed laughter and invite placid slumber to the sound of the lute. Reverently, our kingdom is not of this world, for though art may make the Sybarite, science never, and "then too," rejoins the cynic, "there may be no more sleep upon a bed of down than upon a pallet of straw, no more content with millions than the frugal meal with much liberty." "Anyhow," continues a modern Diogenes, "we could much better enjoy our outing were it not for that ponderous book of questions so pompously borne in our rear."

THE PATHOGENESIS OF LOCOMOTOR ATAXIA.

Presented to the Section on Neurology and Medical Jurisprudence, at the Forty-eighth Annual Meeting of the American Medical Association held at Philadelphia, Pa., June 1-4, 1897.

BY L. HARRISON METTLER, A.M., M.D.

CHICAGO, ILL.

The gradual attainment of our present knowledge of the disease known as locomotor ataxia, is one of the fascinating stories of medicine. While it is undoubtedly true, as one writer says, that it is the most common and the best known today of all the nervous affections, and while it is also true that the advances made toward the recent conception of its etiology and pathology have within the last few years been something marvelous, it is nevertheless a fact that after all we have only entered upon its elucidation. Many of the newer discoveries have only added to the complexity of our knowledge. We are almost as much in the dark as ever in regard to the real cause or causes of the trouble, nor have we found as yet any sufficient reason why those causes should exert a selective action upon special nerve areas. One comprehensive definition has it that locomotor ataxia is a degenerative sclerosis of the sensory apparatus, involving this side of the nervous system anywhere from periphery to cortex. But why should the sensory elements be the subject of deleterious influences in this disease more than the motor elements which lie in such close proximity to them, and which so far as we can see are histologically identical? There must be a reason for this, and it is the object of pathology to discover it. In regard to the differences between sensory and motor elements, anatomy is silent and physiology only declares that one is centripetal and the other is centrifugal in function. Even should some agreement be arrived at in regard to the character of the lesion in all cases, whether it is inflammatory, degenerative, interstitial or parenchymatous; and even should a happy conclusion be reached in regard to the much vexed question of etiology, whether it is syphilitic, traumatic, hereditary, sexual, etc., the all important contention still remains as to why these causes should always produce the degeneration, the

sclerosis or the inflammation of the sensory elements as they always do in locomotor ataxia. To be sure they often give rise to similar lesions in other parts of the nervous system, but still they must possess some special influence in locomotor ataxia, since this disease is so much more common than all the other nervous diseases. When one attempts to extensively examine the literature on this subject he is soon overwhelmed with confusion; for he observes that almost every writer promulgates a theory of his own, based largely upon facts and observations interpreted in accordance with his own mental bias and limited experience.

Consider for a moment the etiology of the disease. Syphilis has been assigned as a cause of locomotor ataxia in from 5 to 90 per cent. of all cases, and by equally competent authorities. When in 1876 Fournier first called attention to the wide association of syphilis and tabes, he was severely criticized because his field of observation was chiefly among syphilitics. But Duchenne, who first named and described the disease, in 1864, so that it was thereafter given a place by itself in the text-books, indicated his suspicions of its specific nature by urging the efficacy of the iodid of potash in its treatment. Testimony has been steadily accumulating in favor of the tremendous influence of syphilis as a causative factor until at the present time there is not wanting high authority for the assertion that locomotor ataxia is nothing more nor less than a sequel of lues, and that the cachexia venerea constitutes the background whereon all cases are projected, no matter what may be the exciting cause that starts them into activity.

Möbins of Leipzig declares that tabes is a syphilitic disease. Darkschewitsch of Kazan argues that syphilis must be considered as the cause of the disease because the specific peripheral neuritis (toxic polyneuritis) is the primary trouble, the cord lesion being merely a subsequent secondary manifestation. Blathner of Berlin, points out a sort of crossed action of syphilis in tabes, as revealed in the not infrequent insufficiency of the aortic valves. It is to be noted, however, that though Gowers states that valvular heart disease "is the most important" complication of tabes outside of the nervous system, it has been shown, after a careful study of the question by Bailey, that "while organic cardiac changes occur in a small proportion of cases, their occurrence is not more common in tabes than in any other disease of a senile character." Minor of Moscow, brings forth apparently some strong proof of the syphilitic origin of locomotor ataxia upon ethnographic grounds. Out of a series of 1642 cases of nervous diseases of all kinds among the native Russians, 496 were males and 264 females, while among the Jews, 449 were males and 433 females. Of the male Russians, 25 per cent. were syphilitic; of the females, 11.4 per cent. Of the male Jews, on the other hand, only 7 per cent. were syphilitic, while of the females only 1.5 per cent. had had syphilis. It is strikingly significant, therefore as bearing upon the question of the syphilitic origin of tabes, to find that the latter disease is five times more frequent among the Russians than among the Jews. But note in connection with this the equally significant fact, long ago pointed out by Grimm, that syphilis is particularly rife in Japan, while tabes is exceedingly rare.

Of 1016 optic nerve atrophies examined by Galezowski, 800 were found in tabetic subjects, and more than half of these were syphilitic. In Schwarz's tabulated list of thirty cases of tabes, all were syphilitic. Germeix

insists that syphilis is the cause of locomotor ataxia. Strümpell holds that all cases are due to syphilis, the lesion not being, however, strictly syphilitic, but rather a metamorphosis brought about by the slow selective action of the toxin. Vermeil voices the same opinion, as likewise does Raymond of Paris. Erb's recent list of 500 cases of tabes admitted syphilis in 89.2 per cent., but Erb recognizes the power of other causes acting in conjunction with syphilis, for he enumerates a long and varied list of such causes. Specific disease was found to have been present in 90 per cent. of the 400 cases of Gajkiewicz of Warsaw. Marie of Paris, a pupil of Charcot, who was notoriously conservative in regard to the influence of syphilis, has lately declared that syphilis is practically the only cause of tabes. Truly does experience teach men different lessons!

One fact is certain, however, that syphilis has not yet been established as the only cause of locomotor ataxia. Many advocates of the specific etiology of the disease are forced to admit that there are some cases in which syphilis does not seem to play a rôle. Soon after Fournier had announced his radical views, Teissier of Lyon, took the stand that lues was not a direct, competent cause of posterior spinal sclerosis, though he ranked it as a predisposing cause along with gout, rheumatism, alcoholism, etc. He based his views upon some thirty-five cases, of which only thirteen were positively syphilitic. In 1887 Karger of Berlin, reported that 53 per cent. of 117 cases of tabes were syphilitic. In the same year Nägeli of Zurich studied a list of 1403 cases, and found that 46.1 per cent. were positively syphilitic, while 60.6 per cent. were merely suspiciously so. Gerlach observed among 156 cases of tabes, that 56.25 per cent. of the men and 66.7 per cent. of the women were the victims of specific disease. In contrast with Gerlach's observation it is interesting to note that Andronico examined "great numbers" of prostitutes, of which many must doubtless have had syphilis, but found that locomotor ataxia was exceedingly rare among them. It is currently stated that tabes affects men in proportion to women as ten to one, and all because women are less exposed to the same deleterious influences that men are. But if syphilis be the direct cause of tabes the ratio, it seems, ought to be less than ten to one, even taking into consideration the well known fact that syphilis is not so disastrous to the female as to the male. In six of Andronico's cases, all of which were women, only one had had syphilis. At all events, this disparity between men and women in regard to syphilis and its relation to locomotor ataxia, would seem to indicate that syphilis is not a direct cause of the latter disease, but rather a predisposing or diathetic cause; and that the singular immunity of women is due to their comparative freedom from the direct, exciting causes such as cold, damp, muscular exertion, etc.

That syphilis can not be the only cause of locomotor ataxia is conclusively shown by the case of Leloir, which became a victim of the spinal disease in 1878, and not until five years later, in 1883, was afflicted with syphilis. Bernhardt and Guelliot have both reported cases of tabes, free from specific disease, in which the excessive muscular exertion of running a sewing machine seems to have been the only cause.

Lagondaky estimates that only about 42 per cent. of tabetics have been the victims of syphilis. Kuhn, of the Berlin Charity Hospital, found that syphilis was present positively in only about 37 per cent. of the tabetics, probably in 31, and possibly in 7 per cent.

In 225 cases of the disease, Pitres of Bordeaux could only prove that 55 per cent. of them had been syphilitic. Since there were other causes in operation at the same time, such as heredity, alcoholism, sexual excesses, etc., the syphilitic cases, pure and simple, were reduced to 22.33 per cent. Leyden is still of the opinion that 20 per cent. represents a fair estimate in regard to the number of cases of tabes caused by syphilis. Of 108 cases quoted by Storbeck, 20.4 per cent. were syphilitic, and 58.3 per cent. were non-syphilitic. After all, it would seem as Cardarelli says, that the effect of syphilis in the production of locomotor ataxia has been greatly overestimated.

In a certain percentage of cases the syphilitic toxin may so impair the nervous tissues as to cause them, under some special stimulation, to undergo degeneration and sclerosis. There must be some exciting cause, some determining cause to act upon the general cachectic state produced by the syphilitic toxin, or else it will be incumbent upon the advocates of the syphilitic etiology, such as Marie, to explain, first, why all or at least a larger percentage of syphilitics do not contract posterior spinal sclerosis, and secondly, why this universal wide-spread toxin floating through the blood, selects special parts of the nervous system whereon to expend its force. They must demonstrate a selective power in the toxin or a special susceptibility in the sensory apparatus. Until such an explanation is forthcoming other causes must also be invoked. Among these there have been enumerated heredity, age, sex, cold and damp, sexual excesses, trauma, alcoholism, ergotism, arsenicism, environment and other spinal diseases.

Let us now look at the question from the pathologic side. Locomotor ataxia is recognized today as a much more extensive disease than it was for a long time supposed to be, and from various indications it appears that the distribution of its lesion will be found in the future to be wider than the facts now warrant us in accepting. Indeed, the implication of many of the motor nerves and tracts would seem to be more than a mere extension of the pathologic process from the contiguous sensory structures. Instead of the disease being a purely systematic one, it begins to resemble an extensive form of multiple sclerosis. The names posterior spinal sclerosis and tabes dorsalis are no longer accurate, for the posterior columns are not the only parts of the sensory cord that are affected, while the process is no longer considered an ordinary form of sclerosis; nor is the disease a genuine tabes, confined solely to the dorsal region.

Without reviewing the development of our knowledge in regard to the parts of the nervous system involved in locomotor ataxia I will simply indicate those that are now known to be affected. They are the columns of Goll and Burdach, including the posterior root-zones of Charcot; the direct cerebellar tracts of Flechsig, which many think are the real cause for the ataxia by cutting off the transmission of sensory impressions to the cerebellum, the organ of co-ordination; the antero-lateral columns of Gowers; the columns of Clarke; and the Spitzka-Lissauer tracts near the circumference of the cord on either side of the posterior roots. Structures outside of the cord that have been found diseased, are the posterior spinal nerve-roots, many of the peripheral sensory nerves, many of the encephalic nerves like the optic, trigeminus, abducens, oculo-motor, auditory and spinal accessory, and parts of the cerebral cortex.

Of all the extra-spinal lesions, those of the optic and other ocular nerves are the commonest. Out of 1016 cases of optic nerve atrophy observed by Galezowski, 800 were tabetic. The same author noted as a significant prodromic sign of locomotor ataxia, unilateral paralysis of the muscles of accommodation associated with anesthesia of the corresponding periorbital region, unaccompanied by mydriasis. Kayser of Berlin, found impairment of vision in 35 per cent. of 117 cases of locomotor ataxia in Mendel's clinic, the Argyll-Robertson pupil occurring in 66 per cent. Any number of cases might be cited, all manifesting an early and significant implication of the ocular nerves. The organ of sight, however, does not exhaust all the cranial nerve palsies, and Erb says these cephalic symptoms are present in one-half of all cases of tabes, and are persistent in from one-third to one-sixth.

The auditory apparatus comes in for its share of trouble. In the examination of some forty cases, Marini found that only 17.5 per cent. had normal hearing, while 29 per cent. had some affection of the auditory apparatus. Of the latter, 10 per cent. had middle ear disease, and 37.5 per cent. had undoubted internal ear disease, a condition which was also suspected of the remaining cases. Morpurgo observed that forty-three out of fifty-three cases of tabes had some auditory trouble. Admitting that some of these statistics may be open to question, it is none the less true that impairment of hearing, due to true nerve-deafness, as well as to trophic disturbances in the auditory apparatus, is not an uncommon symptom of locomotor ataxia.

The vagus accessorius and glosso-pharyngeal (Oppenheim) have been found degenerated, along with the extension of the spinal lesion up into the corpora restiformia. Many of the bulbar symptoms have been attributed to disease of the central nuclei, but after a careful investigation Van Gieson concludes that the various crises are really due to peripheral and not to central lesions. He reports a case in which a painstaking autopsy revealed, besides the usual characteristic spinal lesions of tabes, a bilateral chronic diffuse neuritis of the vagus and spinal accessory roots, but without involvement of the nuclei of those nerves.

Ever since Déjerine in 1883 described his case of locomotor ataxia in which there was only a general peripheral neuritis, and in which the cord elements and posterior roots were discovered to be normal, the lesions of the peripheral nerves, with or without accompanying spinal cord lesions, have attracted more and more attention until the extreme view has been advanced (Déjerine) that locomotor ataxia is, after all, a disease primarily of the peripheral nerves, a *neuro-tabes périphérique*. In his own words, Déjerine says that tabes is beginning to present more and more the appearance of a peripheral disease of the sensory and motor, and nerves of special sensation. According to this idea the medullary lesions are the result of a secondary degeneration, and the entire nervous affection is the product of a toxin in the blood.

Leyden, Redlich, Déjerine and Marie have all demonstrated that the primary trouble is in the posterior nerve-roots in their intra-medullary course. Marie sums up these views thus: "The changes found in the tabetic spinal cord are not the results of a primary systematic myelopathy. They are the expression of a progressive degeneration of the posterior root fibers. These medullary changes in tabes occur in segments,

while each diseased posterior root furnishes a new contingent of degenerated fibers to the spinal cord." The question which is still unsolved is whether the origin of the degenerative process is below or above the posterior ganglion. The cause of the degeneration in the posterior roots is supposed by Marie to be a disease of the spinal ganglion cells as well as of the peripheral ganglia. Locomotor ataxia therefore resolves itself primarily into a ganglionic disease induced by a virus. Wallenberg of Halle, and Ransom give strong support to these views of Marie from postmortem examinations made by themselves. Blocq of Paris adds his confirmation also, and furthermore shows the developmental character of the degeneration of the medial portions of the posterior roots, those portions which are the first to become diseased consisting of thicker fibers and developing very early in embryonic life (from the seventh to the eighth month).

Whether this ganglionic theory be wholly true or not, there must be some place of beginning for the disease process. The usual site of this beginning, and the reason for the disease commencing at this site have been the inspiration of many theories and much controversy. That the extension of the disease is an upward degeneration will not, I presume, be disputed by anyone; for clinical as well as pathologic observation prove it. There is a gradual centripetal disappearance of the axis cylinders and medullary sheaths (Adamkiewicz) with accompanying neuroglial changes (Schiefferdecker and Homén). It may not be untrue, as some more recent writers have stated, that the progressive sclerosis of the spinal tracts are, to a certain extent, primarily attributable to an overgrowth of the neuroglia originating in the epiblast, as well as of the connective tissue derived from the mesoblast; so that as Dana says, we may have to speak of the process as a posterior spinal fibro-gliosis. At this point the well known conclusions of Déjerine and Letulle are appropriately recalled. The neuroglial type of sclerosis, according to these investigations, is characteristic of Friedreich's disease, and we can therefore understand the hereditary nature of this form of locomotor ataxia, since it has been proved that the neuroglia is histologically of ectodermic origin and not mesodermic, as is the associated connective tissue. In the neuroglial sclerosis of Friedreich's disease the defect is an embryologic one and not vascular, as it is in the mixed connective tissue type of sclerosis, characteristic of multiple sclerosis, diffuse sclerosis and tabes. The one is an inherited defect, the other an acquired form.

Auscher corroborates these views from an autopsy. According to Tellinek of Vienna, the lesions of the cerebellum found in six cases of tabes, consisted of atrophy of the nerve cells of the dentate body and degeneration of the medullary fibers of the lobules, which to some extent would seem to indicate the parenchymatous nature of the pathologic process.

From past observations the most frequent focus from which the lesions of locomotor ataxia took their start seemed to be in the dorso-lumbar region. Many have been the reasons given to account for this. Long ago, when the lesion was supposed to be of an inflammatory nature (Vulpian, Charcot, Erb), the gravitation and stagnation of the circulation in this part of the cord were advanced as sufficient reasons. Then when sexual excesses were considered as a potent cause of the disease instead of an unfortunate early symptom, their disturbing influence upon the local circula-

tion and over-excitation with exhaustion of the genito-spinal centers were blamed for the trouble starting in this region. The vasomotor theory of Porter based upon organic alterations in the anterior and posterior spinal blood vessels, with consequent disturbance of the local nutrition was certainly ingenious, but hardly tenable in view of the wide extent of the lesion and the similar vascular changes in parts of the nervous system not subject to sclerosis and degeneration. The same criticism applies to Spitzka's explanation in regard to the thickly interwoven minute fibrous network in the dorso-lumbar part of Burdach's columns, as being the reason for the disease originating there. Not even the views of Déjerine, founded upon the existence of a local meningitis and neuritis, nor those of Obersteiner and Redlich, based upon the injury supposed to be caused to the posterior nerve roots, by a syphilitic inflammation and contraction of the membranes of the cord surrounding the roots at their exit, are entirely satisfactory. First, locomotor ataxia is a most extensive disease, and not all cases, by a large majority, begin in the dorso-lumbar, or any other region of the cord; and second, if these various local conditions, invoked as an explanation of the origin of the disease in the dorso-lumbar part of the cord be entirely adequate, why do the same conditions not account for those forms of locomotor ataxia that start elsewhere in the cerebro-spinal system, than in the dorso-lumbar region? For example, how can general organic thickening of the vascular walls throughout the body, or local meningitis determine all of the many varied forms of tabes? How can a peculiar histologic network in a certain part of the cord account for cases that oftentimes seem to originate in peripheral nerves? How can gravitation and local stasis be made to answer for such varieties as cervical tabes? For the frequent forms of tabes that have the origin of their lesion in the dorso-lumbar part of the cord, almost any one of these various explanations would answer; but for the other and irregular forms, they are all untenable. In science a theory is not acceptable unless it is capable of being applied to every individual instance of a series. It does not seem to me that any one of these explanations, applicable as they may be for the dorso-lumbar forms of locomotor ataxia, can be applied in those not uncommon instances (Galezowski and others) in which the ocular so long precede the spinal symptoms; in those (Martins, Déjerine, Finny, Weir Mitchell) in which the cervical symptoms predominate; in those (Trousseau, Déjerine, Gubler, Luys) in which only the peripheral nerves seem to be affected. Indeed, no sufficient explanation for the origin of all cases of locomotor ataxia has yet been proposed. Many of the exciting causes such as trauma, local meningitis and sexual excesses operating in conjunction with a neurotic cachexia do determine the original site of the disease process; but for those insidious, apparently spontaneous cases starting from merely a general cachectic condition of the nervous system, there seems to be no explanation. For the selective implication of the sensory elements in these latter cases it appears very much as though we will have to consider some peculiar cellular structure or alteration or differentiation, some histologic peculiarity in the sensory elements themselves as the real determining cause.

As a result of some embryologic investigations made by Trepinski, under the direction of Flechsig, the latter declares that not only in the posterior columns but

in the posterior nerve-roots as well, the parts that undergo degeneration first in tabes correspond to certain definite embryologic tracts. These tracts are the so-called middle root zones and median zone of the posterior columns. The other fibers from the middle root zone, which in the embryo appear later and seem to go to the columns of Goll, remain intact in tabes. Flechsig's entire article is full of suggestions and seem to point in the right direction for a solution of the question as to the selective action of the cause or causes of locomotor ataxia. Blocq confirms the origin of these tabetic degenerations in certain tracts of the posterior roots, which are developed in the embryo earlier than are some of the adjoining tracts. Can any such differentiation be found between the sensory and motor tracts as to enable us to comprehend why, with such general causes as a blood dyscrasia, locomotor ataxia should always be a disease of the sensory apparatus? It certainly would be a magnificent attainment if we could fully and positively assert as Leyden does, quoted by Obersteiner, that locomotor ataxia is "a chronic atrophic degeneration process of the spinal cord, originating in the posterior roots and connecting itself with distinct embryologic fiber symptoms."

A STUDY OF RETRO-PERITONEAL NEOPLASMS WITH SPECIAL REFERENCE TO DIAGNOSIS.

Read before the Southern Surgical and Gynecological Association at St. Louis, Mo.

BY RICHARD DOUGLAS, M.D.

NASHVILLE, TENN.

Definition.—For the purpose of my paper I accept the limitation suggested by Mr. Lockwood for retro-peritoneal neoplasms. The term implies a solid or cystic tumor growing behind the peritoneum, into its folds and not connected with any of the great retro-peritoneal organs. So we at once eliminate from our consideration tumors of the kidneys, pancreas, uterus and so-called broad ligament ovarian cysts. Neoplasms connected with any of the retro-peritoneal viscera usually present sufficient evidence in their history, symptoms and physical signs to enable us to ascribe their site of origin.

Origin.—Surgeons are not very careful in determining at the time of operation the true origin of the tumor with which they are dealing. The spirit of the pathologist is for the time eclipsed by the surgical emergencies. Therefore, I feel safe in assuming that many retro-peritoneal neoplasms have been encountered, the surgeon, recognizing the inoperable character of the case or awed by the apparent insurmountable difficulties, abandons the attack and consigns the patient and the diagnosis to oblivion. The structures involved primarily in these growths are the retro-peritoneal cellular and fascial tissue, retro-peritoneal and mesenteric glands, the sheaths of the great blood vessels and the vertebræ.

Pathology.—The type of tumor usually encountered in the retro-peritoneal space belongs to the connective tissue group. A careful study of these cases shows that they are of a mixed variety, the predominating type being sarcoma and lipoma, occasionally fibroma and myxoma are seen. An analysis of the twenty cases of solid retro-peritoneal tumors collected by Rogowski showed sarcomatous tissue in every one.

The peculiarity of retro-peritoneal sarcomata is that they are encapsulated. According to Mr. Cripps, they do not recur when removed. From a careful

investigation of the literature on this subject I think the speaker was safe in making this assertion inasmuch as about 95 per cent. of the patients die from the operation or before it.

The predominating microscope picture is generally of the spindle cell sarcoma, yet in literature we see such descriptive terms as myxo-sarcoma, lipo-sarcoma, fibro-cysto-sarcoma, etc. Metastasis occurs in about one-half the cases, the liver, lungs and mesenteric glands being the parts involved.

Frequency.—There seems to be a general understanding among surgeons that these tumors are so rare that they are scarcely worth special study, and this is borne out somewhat by Mr. Lockwood, who says that no specimen of retro-peritoneal sarcoma has been exhibited in the Obstetrical and Pathological Society of London, and prior to 1895 the Medical Society of London had no opportunity of discussing this peculiar pathology, yet in 1889 Rogowski was able to collect twenty cases. In a recent discussion in the Royal Medical and Chirurgical Society of London, Mr. Shield reports a very instructive case of retro-peritoneal sarcoma and from the limited discussion that it elicited one would infer that the members were quite unfamiliar with the subject.

Age.—They occur after maturity, from 28 to 59 years. Mudd's patient, the oldest on record was 71 years. In one case reported by Joseph Austein, the patient was a female 4 years of age.

Sex.—These growths occur alike in both sexes.

Duration.—Duration of life history of retro-peritoneal tumors is usually about six months, though some cases have lasted for years, but usually when the tumor has existed for so long a time the original growth was some form of typical neoplasm and sarcomatous change engrafted upon it. Thus in Waldeyer's case in which the tumor weighed sixty-three pounds, there was some history of abdominal tumor for several years; the microscopic examination showed it to be a lipo-myxo-sarcoma.

Causation.—There is no recognized cause for these growths, yet in some cases the malignant growth appears as secondary to some local injury or suppuration. Rogowski reports a case of Neumann in which tubercular abscesses occurred some ten years before the appearance of a sarcomatous tumor at the site of suppuration. There has been some effort to assign these growths to specific origin, yet we would scarcely expect a gumma in the loose retro-peritoneal tissue without its occurrence in other organs.

Diagnosis.—The difficulty that surrounds the differential diagnosis of abdominal swellings is notorious, and a solid growth that can not be attributed to any of the great organs should at least arouse suspicion. Clearly it is of the greatest importance that we should learn to diagnose these retro-peritoneal tumors before they have seriously affected the health of the patient, acquired such universal attachments, and distorted the abdominal viscera. And it appears that the diagnosis would be much easier in the early stage if the investigation is made under anesthesia.

Retro-peritoneal tumors possess certain well marked characteristics not found in primary intra-abdominal neoplasms. The latter originate primarily between the duplications of the peritoneum, are attached to the organs from which they spring and have their attachment between the intestines and pelvic cavity, while retro-peritoneal tumors "originate in the retro-peritoneal space and as they develop they encroach

upon the peritoneal cavity, and push the organs contained therein either forward or to the side, in a most typical manner." (Witzel).

General condition.—A patient bearing a retro-peritoneal tumor exhibits pronounced constitutional disturbance. The usual large size of the tumor and its location, give rise to disturbances of the digestion and respiration. The kidneys are frequently displaced and compressed by the growth, the spleen is entangled in the mass and the blood vessels and lymphatics of the digestive tract are partially obstructed. Consequently these patients are usually emaciated, suffer from intermittent diarrhea and not infrequently with nausea and vomiting and gradually a pronounced cachexia is developed.

Such a growth, whose history does not extend over a period of a year, frequently a much shorter time, develops this condition more rapidly than in ordinary intra-abdominal tumors.

Morphology.—The appearance of the abdomen in these growths is by no means characteristic. They grow anteriorly, as VanderVeer says, in the direction of least resistance; yet the size and location has much to do with the morphology.

In Mudd's interesting case the abdomen was exceedingly pendulous, the tumor resting on the patient's thighs. In other cases the contour of the abdomen is very striking, the tumor causing great swelling in the upper portion and bulging but little in the side or below the umbilicus.

In the interesting case of lipoma reported by Terrier and Guillemin, this characteristic appearance of abdomen was exceedingly striking. These tumors are usually asymmetrical and frequently extend into the pelvis, in one instance producing complete uterine prolapse. The direction of the growth of the tumor alters the appearance.

The superficial veins of the abdomen are usually very much enlarged, a fact easily accounted for, both by the pressure of the tumor upon the vena cava which frequently occurs, and by the distortion of the mesenteric veins due to displacement of the viscera.

Contrary to what one would suppose, these tumors are sometimes decidedly influenced by respiration. In Ransohoff's case, a very large tumor which lay chiefly on the right side intimately connected with the liver, was moved distinctly with each respiration. This phenomena was evidently confusing to the surgeons. As a general rule, however, these tumors are not influenced by respiration.

Palpation.—These tumors, whether lipomata or sarcomata, do not give upon palpation the elasticity or fluctuation observed in a tumor with fluid contents, and certainly not that hardness observed in ordinary uterine fibromata. Lipomatous tumors, particularly, impart upon palpation a special feeling which may be likened to that of the liver. (Terrier and Guillemin.)

Tumors that grow from the root of the mesentery and develop between its folds are very movable, but those attached along the vertebra or in the retro-peritoneal spaces of the flanks are fixed.

The surgeon, in palpating these tumors, must bear in mind that many of these solid growths are undergoing cystic changes and this alteration sometimes deludes, as the tumor does not present a uniform density upon manipulation. It is a well known characteristic of lipomatous tumors in any part of the body to impart on palpation a deceptive sense of fluctuation.

In Mudd's, Ransohoff's and Guillemin's cases of large retro-peritoneal lipomata fluctuation was apparently distinct. This sign together with the lobulated character of the tumor is confusing and more than once has lead the operator to mistake it for multilocular ovarian cyst, especially of the type of cyst described by Rokitsansky.

Percussion.—This is our most reliable method of diagnosing these tumors. In all retro-peritoneal tumors whether they originate close to the vertebra or to the side, their growth is usually laterally and in these cases, according to Witzel, the colon bears a most typical and diagnostically important relation to the tumor. At first, while yet the tumor is small, the colon is external, later it is pushed forward and lies in front and, finally, the tumor attaining great dimensions and still growing laterally, the colon lies centrally in front of the tumor. Appreciating this fundamental fact we can intelligently apply our physical test of percussion.

Barring the relation of the colon, as above expressed, these tumors are usually dull upon percussion. And unless they are very large and project into the pelvis there is usually an area of resonance between the tumor and the symphysis. When situated upon the right side their relation and connection with the liver is so intimate as to efface any area of resonance between that organ and the tumor. When large the resonant area is upon the side opposite to the tumor or that part of the abdomen occupied by the displaced intestines. The relation that the colon bears to the tumor can be easily determined by inflation of the gut with gas. Unless this precaution is taken the ordinary pressure applied with a pleximeter or hand, in making mediate percussion, may cause a dull note. Percussion does not always yield the same note in any individual case. In the second case reported by Lockwood, immediately after admission to the hospital the tumor was dull upon percussion; it grew rapidly in the next fortnight and was decidedly resonant. This was explained at the operation; the growth of the tumor being rapid it extended into the mesentery, separated it widely and the intestines which were at first laterally displaced were now by the growth of the tumor, elevated and distributed over its surface.

From this clinical observation I would draw the following conclusion, that intra-mesenteric tumors may be resonant upon their upper surface and the dullness marked in the flanks, a condition closely resembling ascites. Furthermore, it is a clinical feature of retro-peritoneal growths that the area of resonance varies with the position of the patient. Consequently it is not surprising that many a dry tapping has been made through a failure to recognize these clinical peculiarities.

While not an advocate for the use of the aspirator in intra-abdominal diagnosis, yet under proper conditions this instrument will reveal valuable evidence, not only as to whether the growth is solid or cystic, but as to its nature. In retro-peritoneal sarcoma aspiration reveals only a little blood or bloody serum in the needle. This sign was one of the convincing points that enabled Wier and Bull to correctly diagnose a case reported by Devlin. In lipoma, on account of the slight vascularity of the growth, no blood is withdrawn. By puncture of ordinary cysts, whether mesenteric, kidney, ovarian or echinococcal, characteristic fluid will appear in the canula.

Blood in the urine.—In only one case in which the

kidney was not involved is there recorded any change in the character of the renal secretions. Usually there is entire absence of blood in the urine of these cases.

There are two special symptoms that occur in the history of post-peritoneal growths deserving of mention. First, the occurrence of intestinal obstruction which has been noted in the history of many cases. Witzel records a case in which volvulus is diagnosed but the patient was suddenly relieved. She was pregnant at the time, and after the termination of her labor, a large swelling still remained in the abdomen which reached to the umbilicus. Again symptoms of obstruction came on, operation was attempted but the tumor was too deeply imbedded in the structure of the loin to attempt its removal. Autopsy showed it to be a retro-peritoneal sarcoma. While volvulus is mentioned in many cases, the condition does not usually advance to that stage. There are numerous attacks of partial obstruction, due to intestinal distortion, giving rise to pain, nausea and vomiting, symptoms relieved as soon as free evacuations are obtained.

The second special symptom that I wish to emphasize is edema of the extremities. It is a symptom that may occur very early in the history of the growth; it is due to pressure on the vena cava and should materially aid us in making a diagnosis.

While we have attempted to analyze the special symptoms present in retro-peritoneal growths, yet we must admit that no one is pathognomonic and a diagnosis must be reached by exclusion.

Complications.—The most serious complication attending these retro-peritoneal growths, and one that indicates usually peritoneal metastasis or serious obstruction to the circulation, is ascites. This, together with the distension due to distortion or pressure, usually characterizes the closing scene of the case.

Prognosis.—The prognosis in lipoma and other forms of innocent or typical tumors is ultimately as grave as in sarcoma. The disturbance of digestion, respiration, circulation and lymphatics sets up a condition that soon undermines the constitution. The relative benignity of these tumors justifies, in all cases, an exploratory operation. In intra-mesenteric growths of all forms, the prognosis is necessarily grave. The injury to the circulation, the devitalization of the peritoneum and the difficulty attending the enucleation and often the necessary resection of the intestine, renders the operation an exceedingly grave one.

RETRO-PERITONEAL CYSTS.

A generic classification of retro-peritoneal cysts is even more difficult, in view of our meager knowledge of the subject, than that of solid neoplasms. Adhering to our original idea of considering only tumors disconnected with the great viscera, we find four varieties of retro-peritoneal cysts: 1, retro-peritoneal cysts with chylous-like contents. These are cysts of the lacteals which, by retention and rupture, give rise to true mesenteric cysts containing chyle; 2, retro-peritoneal serous cysts (Prizewoski); 3, dermoid cysts which originate in the structures which persist from fetal life; 4, traumatic cysts (Schonwerth).

Pathology.—Large cysts with chylous-like contents have frequently been found. Their retro-peritoneal nature is unmistakable, from the relation they bear the colon and mesentery, and in one remarkable instance the tumor lay behind the kidney. These tumors bear a very intimate relation to the mesentery: they are separated from the liver.

The origin of these cysts is in the lacteals, or they may, by accident or disease, have some connection with the thoracic duct itself. The character of the contents is the interesting feature of their pathology and diagnosis. Perhaps one of the most carefully observed and accurately recorded cases is that by Gustav Kilian. This surgeon, after many attempts to obliterate the sac by aspiration, finally cured the patient by operation. The fluid in its macro- and microscopic examination and chemic analysis very closely resembles milk.

A second form of retro-peritoneal cyst deserving, perhaps, more attention than it has received, is the retro-peritoneal serous cyst, originally described by the pathologist Prizewoski. A complete summary of all knowledge we possess on this variety of cysts may be found in the dissertation of Dr. A. Ohelinski, in Krakau. He concludes: 1, that retro-peritoneal serous cysts, while not often observed, are not of such great rarity. The reason of this is lack of, or faulty knowledge of the existence of such growths; 2, they are cysts of slow evolution; 3, their origin is, according to Prizewoski, the Wolffian or Müllerian bodies; 4, they are innocent in their behavior; 5, contents clear, serous fluid; 6, extirpation is a simple operation, comparatively free from danger.

The parasitic, dermoid and traumatic cysts, the three other retro-peritoneal forms, possess nothing peculiar or distinctive because of their special location and do not require further consideration.

Differential diagnosis.—The exclusive or differential diagnosis of retro-peritoneal tumors from conditions which closely simulate them is perhaps one of the most difficult problems in surgery. A conclusion can only be reached by systematic investigation of each individual abdominal organ and its function, and in a careful study of the tumor itself, its physical characteristics, its relations, and with the assistance of the aspirator, a careful microscopic and chemic analysis of its contents.

Retro-peritoneal tumors must be differentiated from every form of tumors found within the abdomen, but we encounter particular difficulties in distinguishing these growths from tumors of the kidney, cysts of the pancreas, uterine and ovarian tumors.

Kidney and retro-peritoneal tumors possess certain features in common. They are both retro-peritoneal, in both the large intestine lies in front, both are dull between the tumor and vertebral spines, no space between the kidney or tumor in which the fingers can be dipped, both grow anteriorly, consequently there is no prominent lumbar projection. Respiration influences either tumor but slightly.

Retro-peritoneal tumors that grow between the mesentery are movable, all other forms are firmly fixed. Kidney tumors, unless inflamed, can be moved laterally and upward, and whether solid or cystic, no matter what the size, retain some, often much, of their natural outline; the kidney has no sharp edges. Retro-peritoneal tumors affect but little the normal function of the kidney. In renal tumors there is alteration in the character and quantity of the urine and finally if the tumor be cystic the aspirator will reveal the characteristic fluid in either case.

Cysts of the pancreas.—Cysts of the pancreas are also resonant upon percussion. They underlie the stomach, usually, and push the colon down. The tumor is generally in the epigastric or left hypochondriac region. It is not upon the physical signs,

however, that we rely for differentiation. Cysts of the pancreas have been found only in adults, retro-peritoneal cysts may occur at any age. Pancreatic cysts are very painful, patients suffer with colicky pains in the epigastrium often of great violence; they have fatty stools, are frequently jaundiced; their digestion is impaired; there is rapid emaciation; the skin becomes pale and yellow, a symptom said to be pathognomonic. Diabetes mellitus is occasionally associated with pancreatic disease. These phenomena are, with exploratory aspiration, sufficient to discriminate the case.

Küster emphasizes the great value of inflating the stomach and colon as a means of developing the relation of pancreatic swellings.

Tumors of uterine or ovarian origin assume any dimension and position in the abdomen and differential diagnosis of these from the tumors under consideration can only be made by thorough investigation into the history and subjective symptoms, and by careful vaginal and abdominal examination and conjoined manipulation.

The majority of retro-peritoneal tumors are revealed only at operation and it appears that they are more frequently mistaken for ovarian or uterine tumors, perhaps because of the frequency of these growths.

ADDISON'S DISEASE: TWO CASES IN ONE FAMILY.

BY LY. W. SCHWAB, PH.G., M.D.
CHICAGO, ILL.

My object in reporting this case is its rarity, difficulty of early recognition and the fact that two brothers died from this disease within thirteen months of each other.

I will first give the younger brother's case.

Mr. C., aged 55 years, married, Spanish descent, salesman in wholesale drygoods house.

Family history.—Father is 82 years old and in good health, though he had a slight cerebral hemorrhage last winter, but entirely recovered. Mother died at 62 years of age, from fatty degeneration of heart and kidneys. The necroscopic report does not give any

clue as to the cause. An elder brother died, at 57 years of age, from Addison's disease. One brother, still living, is 45 years old and in fair health. Two sisters died in childhood from scarlet fever.

Patient's history.—Average weight 165 pounds, dark and sallow complexion and troubled with chronic constipation; moderate smoker and user of alcoholic liquors. Previous health always good with the exception of the constipation. Health began failing about eighteen months before his death, the first indication of which was a general progressive weakness, anemia, followed by emaciation. In May, 1896, he took a two weeks' vacation, then returned to work feeling some better.

He seemed fairly well until July 17, when he had a severe attack of vomiting and diarrhea lasting four days. This then ceased for about ten days, when he was again taken with diarrhea lasting three or four days. The alternation of diarrhea and constipation, or normal condition, continued throughout the whole course of the disease. The diarrhea generally lasted from three to four days and was followed by from ten days to two weeks of normal condition of bowels or constipation.

Vomiting was not a permanent symptom until about six weeks before his death, although he was continually nauseated after eating.

With the onset of the attack of vomiting and diarrhea, a marked numbness of the hands and wrists occurred, which lasted several days. After this passed off the feet and ankles became in the same condition. The numbness of the feet and ankles remained, and this condition extended upward until it reached the crest of the ilium.

The circulation was quite feeble and sluggish from the beginning. The appetite was good and at times almost ravenous. There was no pain, though he suffered from extreme exhaustion.

In January, 1897, he suffered from a general eczema, most marked over the back, which lasted about three weeks. The skin became bronzed in color about four months after his health began to fail. It varied in shade, at times being darker than at others, and on the parts where the eczema had been prominent it was darkest. The urine was negative.

After March 28 he was confined to bed. From this time on there was frequent vomiting besides nausea.

On and after March 30 he was unable to void urine. This was probably due to atony of the bladder. By this time the anemia had become very marked and he was also very much emaciated.

Treatment.—The treatment was principally symptomatic. The diet was largely milk, beef juice, eggs, clam broth and fruits. Massage was used on the limbs but had no appreciable effect. Catheterization was employed to empty the bladder.

In medicines, compound licorice powder in 2 to 4 gram doses in the evening, and occasionally a half bottle of the solution of the citrate of magnesia, mornings, were given for constipation. The eczema was readily cured by means of alkaline drinks and the use of a paste locally, consisting of starch and glycerin. The nausea and vomiting were controlled by aromatic spirits of ammonia in doses of 2 to 4 c.c. The diarrhea was controlled by the use of carbolic acid, tinct. catechu, bismuth subnitrate and chalk mixture. Tonics like iron, quinin, strychnia and arsenic were employed, but with very little effect.

The powdered desiccated sheep's suprarenal capsules

in 0.2 gram doses were used at one time for a couple of weeks, but the general condition seemed to fail so rapidly and the numbness ascended so fast that they were discontinued.

During the last three weeks morphin hypodermatically in 0.016 to 0.032 gram doses were used to produce sleep and alleviate the suffering from cramps in the limbs.

The patient died May 7, 1897, from general asthenia, the end being very quiet.

At the necropsy the suprarenal capsules were found to be almost entirely wasted; what remained was tubercular, as shown by microscopic examination.

The elder brother was a very active business man, having had a responsible position in a wholesale dry-goods house. He had typhoid fever and chronic diarrhea in the army, and it troubled him occasionally ever afterward. He suffered from insomnia for several months prior to the establishment of the disease, after which he slept very well; otherwise his previous health had been fairly good.

His first symptom was impaired vision, which gradually progressed until he was unable to read ordinary print; this afterward became considerably better.

The course of his disease was about two years; with the exception of the longer course, and impaired vision, his train of symptoms were about the same as those cited in his brother's case.

There was no necropsy, but a clinical diagnosis of Addison's disease was made by eminent men about a year before his death.

His trouble had been diagnosed as pernicious anemia, neurasthenia, paresis and cancer of the liver, before the correct diagnosis was made.

Conclusions.—Drs. Osler and Quine both say it is the first instance in their knowledge where two cases of Addison's disease have occurred in the same family. Dr. Quine says children of tubercular parents would probably be more susceptible to Addison's disease, but there is no tubercular history in this family. I am informed that these brothers were very similar in habits and temperaments, and this may have something to do with the hereditary element in this instance.

Investigators have come to the conclusion that the suprarenal capsules, in addition to any other functions they may have, elaborate a substance which has a direct action on contractile power of muscular tissue, and on the muscular substance of the coats of the blood vessels, causing contraction and thus heightening the blood pressure. This probably accounts, at least partially, for the great loss of muscular power, this being so great and apparently out of proportion to the other symptoms of the disease.

449 E. 41st Street.

FORCIBLE STRAIGHTENING OF SPINAL CURVATURES DURING COMPLETE ANESTHESIA.

Read before the Chicago Medical Society, Dec. 23, 1897.

BY JOHN RIDLON, M.D.

Professor of Orthopedic Surgery in the Northwestern University Medical Schools; Senior Orthopedic Surgeon to St. Luke's and Michael Reese Hospitals; Surgeon in Charge of the Home for Destitute Crippled Children; and Consulting Orthopedic Surgeon to the Mary Thompson Hospital for Women and Children.
CHICAGO, ILL.

So much has been published during the past two years in the continental medical journals and in the

daily newspapers about the new French method of treating Pott's disease that we feel warranted in briefly narrating the facts and in critically discussing this new surgical procedure.

Spinal curvatures are, broadly speaking, of four kinds: 1, simple posterior curvatures; 2, anterior curvatures; 3, lateral curvatures; and 4, the posterior curves or angles of spinal caries.

As to the first class of simple posterior curvatures, or the ordinary round shoulders most frequently seen in adolescence and old age, and the posterior curvatures of rachitic infants, nothing so far as I know has been attempted in the way of immediate and forcible straightening under anesthesia.

As to the anterior curvatures, again nothing has been attempted. Indeed cases of this class are seldom met with even by orthopedic surgeons of large experience, and their pathology is not well understood.

As to lateral curvatures of the class ordinarily called "rotary lateral curvatures" or "true lateral curvatures"

FIG. 1.—A case of scoliosis.

which we orthopedic surgeons denominate scoliosis, I have seen no reports in the medical journals. These cases of scoliosis should be considered as quite apart from postural lateral curvatures and from the lateral curvature, either with or without rotary deformity, which often precedes the posterior deformity of spinal caries and at times accompanies the posterior deformity in cases of some years standing. Figure 1 shows a well developed case of scoliosis. Figures 2 and 3 show lateral curvature with rotary deformity in a case of spinal caries (tubercular spondylitis) prior to the development of any posterior curve or angle in the spine. Figures 4 and 5 show lateral curvature with rotary deformity in a case of tubercular spondylitis of many years standing and with well marked posterior angular deformity.

I have attempted forcible correction of the deformity, under anesthesia, in five cases of scoliosis. Two cases were at Michael Reese Hospital, girls of 14 and

17 years of age. The curvatures were of the ordinary right dorsal variety, of moderate degree of severity and of several years duration. In each instance I succeeded in reducing the deformity by about one-half. One case at St. Luke's Hospital, a girl of 17 years, with a right dorsal curvature of extreme severity and exceedingly rigid, and of many years duration. In many respects it resembled the case shown in Fig. 1, but the deformity was greater, the spine was stiffer, the shoulders more displaced to the right, and the deformity of longer duration. I succeeded in reducing the deformity somewhat more than one-third and made the patient taller by an inch and a quarter.

The fourth case was at the Home for Crippled Children. A girl of 15 years with a very severe left

23, 1897, under complete anesthesia, I used great force in the way of straightening the curvature. Tearing and crackling sounds were abundant and great straightening resulted. The patient was suspended by the feet and a plaster jacket applied. She was then kept in bed for three weeks, when the operation was again repeated with further gain in the way of straightening. Figure 7 shows this gain, which in height amounts to about three inches.

The fifth case was a girl 7 years old, with well-marked right dorsal scoliosis. Deformity has been noticed since the child was six months old. The deformity is believed to be rachitic. On Dec. 15, 1897 at the Home for Crippled Children this curvature was forcibly straightened under anesthesia to

FIGS. 2 and 3.—A case of tubercular spondylitis simulating scoliosis; shows lateral curvature and rotation deformity.

FIGURE 3.

dorso-lumbar curvature of more than three years duration. Figure 6 shows this case. The pathology is perhaps uncertain. It is a case that most surgeons would unhesitatingly pronounce scoliosis; nevertheless the patient's mother died of consumption; the spine was very stiff for the known duration of the disease; she was not comfortable when lying on her back, and there was pain on pressure over the lower dorsal and lumbar portions of the spine. I do not, even at this time, feel sure as to whether this case is one of tubercular spondylitis or a simple scoliosis.

For nine weeks she was kept in bed with horizontal head-traction of four pounds. The spine became somewhat more flexible, but scarcely straighter. June

about two-thirds its extent. The patient is still in the first plaster jacket, and in bed.

In none of these five cases did any unpleasant symptoms result from the forced straightening.

Finally, as to the posterior curves and angles of spinal caries, that is to say, the deformities of tubercular spondylitis or Pott's disease. It was in this class of cases that the work of forcible straightening under anesthesia was commenced by Dr. Calot, of Berck-sur-Mer. Being dissatisfied with the results obtained by the ordinary methods of treatment, Dr. Calot argued that there appeared no good reason why a tubercular spinal joint should not be treated on precisely the same principles as a tubercular joint in any other part of the body, as the knee or the hip; that

inasmuch as it is customary to straighten deformities resulting from hip disease and knee disease by forc-

without a cutting operation, it would be perfectly feasible and wholly justifiable to do the same operation for the correction of the deformity resulting from the same disease in the spinal bones and joints.

I do not know just what the "ordinary methods of treatment" were with which Dr. Calot became dissatisfied, but if they were the same that one usually finds in France it is not surprising. Even in this country those surgeons who have depended upon the unqualified surgical instrument maker to measure for and fit braces and those that have placed their reliance upon the plaster jacket as a support in ambulatory cases have hardly been satisfied with the results obtained.

Dr. Calot's methods have been followed, with certain modifications, by many of the continental surgeons. It is not necessary here to name them or

FIG. 4.—An old case of tubercular spondylitis, with posterior, lateral and rotary deformity.

FIG. 5.—The same case shown in Fig. 4, stooping forward, viewed from the rear, showing by the parallel lines, *a* and *b*, the degree of lateral deviation; showing also the amount of rotary deformity.

FIGS. 6 and 7 show case No. 4 of lateral curvature, forced straightening, and four weeks later after second forced straightening.

specify their modifications. Sufficient to say, that in recent cases the straightening was effected by longitudinal (horizontal) traction and counter-traction, by the hands of assistants or by mechanical devices, while the operator made manual pressure in the direction of straightening the kyphosis. In older cases operative measures were added. The soft parts were cut through and the bones divided by chisel in one or more places, abscesses were evacuated and cheesy foci cleaned out when such were accessible; then the deformity was straightened and the spinous processes were wired to each other to maintain the corrected position. Immobilizing dressings were applied, and the patient was kept recumbent in bed for many months.

This idea of forcibly straightening the kyphosis of Pott's disease did not originate with Dr. Calot, though he may not be aware of the fact. On Dec. 22, 1890, Dr. B. E. Hadra, of Galveston, Texas, straightened a fractured spine and wired the spinous processes. Commenting on the case in the *Times and Register*, May 23, 1891, he says: "I can not resist the temptation to connect my device also with the treatment of Pott's disease. Here, too, the indication in cases where the abscess or carious bones do not call for other surgical attempts, is mainly to steady the vertebral column in order to protect the cord, to prevent the diseased bones from rubbing on each other, and finally to make the outcome, in regard to disfigurement, as favorable as possible. Judging from my concededly limited experience, and from theoretical deductions, the proposed procedure will do better than braces, corsets, plaster jackets and the like. It seems to me called for as soon as displacement of the bones is noticed; but even if a full kyphosis should be established, it will be proper to put the patient under anesthetic, and to wire to-

ders, when allowed to hang down, is but small, and such cases are more likely to be made straight by succussion with the feet hanging down, since the inclination downward is greater in this way. When the hump is lower down, it is more likely in this case that succussion with the head downward would do good. If one then should think of trying succussion, it may be applied in the following manner: The ladder is to be padded with leather or linen cushions, laid across, and well secured to one another, to a somewhat greater extent, both in length and breadth, than the space which the man's body will occupy; he is then to be laid on the ladder upon his back, and the feet at the ankles are to be fastened at no great distance from one another, to the ladder, with some firm soft cord, and he is further to be secured, in like manner, both above and below the knee, and also at the nates; and at the loins and chest, loose shawls are to be put around in such fashion as not to interfere with the effects of succussion; and his arms are to be fastened along the sides of his own body and not to the ladder. When you have arranged matters thus, you must hoist up the ladder, either to a high tower, or to the gable end of a house; but the place where you make the succussion should be firm, and those who perform the extension should be well instructed, so that they will let go their hold equally to the same extent, and suddenly, and that the ladder may neither tumble to the ground on either side, nor themselves fall forward. But if the ladder be let go from a tower, or the mast of a ship fastened in the

FIGURE 10.

FIGURE 11.

gether the spinous processes, provided that the column can be straightened to a satisfactory extent."

Again in the *Medical News*, Nov. 28, 1891, Dr. Hadra says, "But if an abscess cavity has already formed, the surgeon will have to decide whether or not its dimensions are too great to be filled up by new bone formation. If the abscess cavity is too large it may be better to allow the diseased surfaces to come in contact and to unite by bony ankylosis with kyphosis. Under such circumstances the wiring will be out of place. Not so, however, if the destruction of the bodies and of the inter-vertebral discs is moderate. We may then hope for the reproduction of a sufficient amount of bone, and by holding the spine in a straight line we shall obviously enforce a desirable final outcome."

Forced straightening, without a cutting operation, and without an anesthetic is an idea so old that it has practically been forgotten. Hippocrates writing 500 years B. C. spoke of it as an old method, so old then that the name of the author had been forgotten. He says:

"Those cases in which the gibbosity is near the neck, are less likely to be benefited by these succussions with the head downward, for the weight of the head and tops of the shoul-

ground with its cordage, it will be still better, so that the ropes run upon a pulley or an axle-tree." (Dr. Adams' translation, Sydenham Ed., and Bigg's "Orthopraxy.")

Hippocrates, however, seems to favor the treatment of gibbosities by extension. Here is his method:

"Something like an oaken bench, of a quadrangular shape, is to be laid along at a distance from the wall [in which there had previously been scooped an oblong furrow], which will admit of persons passing around if necessary, and the bench is to be covered with robes, or anything else which is soft, but does not yield much. The patient after being stoved and bathed with hot water, is to be stretched upon the board upon his face, the arms being laid along and bound to the body. Next the middle of a thong which is soft, sufficiently broad and long, and composed of two cross straps of leather, is to be carried across the patient's breast, as near the armpits as possible, then what is over of the thongs at the armpits is to be carried around the shoulders, and afterward the ends of the thong are to be fastened to a piece of wood resembling a pestle; they are to be adapted to the length of the bench below the patient, and so that the pestle-like piece of wood resting against this bench may make extension. Another such bond is applied about the knees and the ankles, and the ends of the thong fastened to a similar piece of wood; and another thong, broad, soft, and strong, in the form of a swathe, having breadth and length sufficient, is to be bound tightly about the loins, as near the hips as possible; and then what remains of the swathe-like thong with the ends of the thongs, must be fastened to the piece of wood at the patient's feet, and extension in this fashion is made upward and downward, equally, and at the same time in a straight line."

The physician is further recommended to press the

palm of the hand upon the hump while extension is being made; or a person may sit upon the hump, rising up from time to time, and letting himself fall back upon it. Or a foot may be placed upon the hump and the entire weight of the body brought gradually to bear upon it. Or better still, a lever may be used, one extremity of which is fixed in the hole in the wall (previously scooped out). The lever is brought to bear across the hump, a cushion being interposed, and firmly pressed down while extension is made. (Dr. Adams' translation, and also Bigg's "Orthopraxy.")

Ambroise Paré, in the sixteenth century, followed the teaching of Hippocrates in the essential principles. He made traction and counter-traction by towels, in place of leather thongs, and assistants, in place of the mechanical device; and he discarded the lever, making pressure with his hands, or with "two pieces of wood, four fingers long, and one thick, wrapped more or less in linen cloths, and so to apply one on each side of the displaced vertebra, and so with your

FIG. 12.—The treatment of spinal deformities by succussion. From the Venetian edition of Galen. Quoted in Bigg's "Orthopraxy."

hands to press them against the bunching forth vertebra, until you force them back into their seats, just after the manner you see before delineated."

It would appear from the above that the only thing new in "the new French method" is the use of the anesthetic, the cutting operation, which is being rapidly abandoned, and the wiring of the spinous processes as recommended by Hadra, which has not yet been demonstrated to be of the slightest value, and appears to add greatly to the discomfort of the patient and to the risk in the treatment of these cases.

European surgeons are becoming more conservative in their work of forcibly straightening spines than they were some months ago, since deaths have occurred from tubercular meningitis and from general tuberculosis arising apparently from dissemination of the disease by tearing through the protecting wall of the tubercular focus, as has occurred after forcible straightening at hip and knee. They are now more inclined

to straighten gradually at several sittings instead of attempting to obliterate the deformity at once.

The procedure is as follows: The patient being fully anesthetized, lies face downward upon a table. The hips and the upper portion of the chest may be raised on padded blocks or supported by assistants. Traction is made downward on the legs by assistants or from a girdle around the pelvis by means of some mechanical device, while traction is made upward on the arms and head by assistants or by a girdle around the chest, above the kyphosis, and the aid of some mechanical device. Corrective pressure is brought to bear upon the kyphosis by the hands of the surgeon. When as much correction has been had as is thought safe, some immobilizing device is applied to the spine to maintain the corrected position, usually plaster-of-Paris is used. This is applied by some while the patient is still horizontal; by others (Bilhaut and Levassort of Paris) the patient is suspended by the feet during the application of the plaster dressing. The objections to the prone, horizontal position are that it requires many assistants, favors lordosis above and below the kyphosis, and is a difficult position

FIG. 13.—Forced correction of spinal curvature by traction and counter-traction, and direct pressure by lever. From the Florentine edition of Galen. Quoted in Bigg's "Orthopraxy."

when the head must be included in the plaster dressing, as it should be when the disease is at or above the ninth or tenth dorsal vertebra. With the patient suspended by the feet few assistants are necessary, and the head is readily included in the plaster dressing, but suspension by the feet causes the abdominal contents to fall upward against the diaphragm and the jacket constricts uncomfortably when the horizontal posture is resumed.

I have attempted this operation on cases of Pott's disease only seven times. I find parents rather disinclined to submit their children to the operation.

Case 1.—Female, 5 years old, well marked dorsal kyphosis (see Fig. 15). The deformity had been present for more than two years, and for the first eighteen months of this period had increased rapidly. No abscess was made out. On July 15, 1897, at St. Luke's Hospital, the spine was straightened to the extent shown by the second tracing. Horizontal traction and counter-traction was made by two assistants to not more than forty pounds (estimated), and very little direct pressure upon the

kyphosis was necessary to reduce the deformity to the degree indicated by the tracing. The tracing was made as the patient lay upon the table after traction had been discontinued. A plaster jacket, not including the head, was applied with the patient held horizontal. Immediately afterward the patient stopped breathing; the jacket was split open, and breathing was resumed. It was left gaping about an inch. Two weeks later when this jacket was removed there was found to be about two-thirds of the original deformity present. The operation was repeated and another jacket was applied, not including the head. At the end of three weeks this jacket was removed and a pressure sore the size of a dime was found over the most prominent spinous process, and there had been some return of deformity. A jacket well padded with felt to protect the spinous processes was now applied with the patient in the prone horizontal posture and without the administration of an anesthetic. The pressure sore readily healed. The spine was again straightened during anesthesia, the patient suspended by the feet and a plaster dressing applied, including the head. The patient is perfectly comfortable and spends much of the day, lying prone and raised on her elbows, in play with toys and the other children.

FIG. 14.—Correction of spinal curvatures by traction and counter-traction and manual pressure upon the kyphosis. From Ambrose Paré, in the sixteenth century. Quoted in Biggs's "Orthopraxy."

Case 2.—Male, 13 years old, inmate of the Home for Crippled Children, where he has been for four years. There is no history of the case prior to his coming to the Home. During the past four years he has had no treatment, but the deformity has not increased. July 21, 1897, I attempted to straighten this spine under complete anesthesia and in the manner already described. Nothing was accomplished after using as much force as seemed safe.

Case 3.—Female, 4 years old, severe upper dorsal curvature with marked forward projection of the chest. The duration of the deformity is not known. An attempt was made to straighten this case, in the usual way, July 21, 1897, at the Home for Crippled Children. Nothing was gained after using as much force as seemed safe.

In neither of these cases, 2 and 3, were there any unpleasant symptoms as a result of the attempts at straightening.

Case 4.—Male, 4 years old, lumbar kyphosis (see Fig. 16) of one year's standing, complicated with an intra-pelvic psoas abscess that flexed the thigh to a right angle. Tuberculosis in the mother's family. July 21, 1897, at the Home for Crippled Children, this spine was practically straightened (see Fig. 16).

The correction has been maintained, no unpleasant symptoms have arisen; the psoas abscess has descended upon the anterior and inner aspect of the thigh, and the thigh is now nearly free from flexion deformity. The jacket has been changed without an anesthetic.

Case 5.—Female, 2½ years old, with lumbar kyphosis of more than six months' duration. The spine was completely straightened at St. Luke's Hospital, Sept. 27, 1897. The jacket has since been changed without an anesthetic, and there is no return of deformity.

FIG. 15 shows tracing (reduced) of spinal curvature before and after straightening in case No. 1.

FIG. 16 shows tracing (reduced) of spinal curvature before and after forced straightening in case No. 4.

Case 6. Boy, 5 years old, left dorso-lumbar curvature of more than three years' duration; very rigid in all directions: muscles rigid in involuntary spasm, and girdle of clonic spasm on any movement or other irritation. Unquestionably a spondylitic deformity, although he has been treated for scoliosis. Dec. 21, 1897, at St. Luke's Hospital, patient under complete anesthesia, three fourths of the deformity was effaced and patient put up in plaster. There has been increased restlessness at night, but no increase of conscious pain. The plaster dressing is still on.

Case 7.—Girl, 6 years old, lower lumbar spondylitis with well marked kyphosis of more than two and one-half years' duration. There is a sinus in the left loin, from a lumbar abscess, of some months' standing. Dec. 28, 1897, at St. Luke's Hospital, patient under complete anesthesia, the spine was more than three-fourths straightened, in the usual way.

In none of these cases have there been any unpleasant symptoms, except as stated in Case 6.

From this slight experience, and from a study of the reports from abroad, I am inclined to the following conclusions:

1. Cases of scoliosis can be safely attempted, and can always be somewhat and often greatly improved by this method of treatment; and no unpleasant results are to be anticipated. It is best to straighten by horizontal traction and counter-traction and by a rotary pressure upon the curvature. During the process of straightening, that is to say, between the operations, patients should wear permanent plaster jackets, extra long, and remain in bed. The jackets will best be put on during suspension from the feet or knees, and complete anesthesia must be maintained until the plaster has set. The feet or knees should be protected from constriction during suspension by plaster stockings applied the day before the operation.

2. In cases of tubercular spondylitis, old cases, where the inflammatory process has ceased and ankylosis has resulted, should be left alone. Any gain in such cases is doubtful, and if accomplished is had at a great risk.

3. Recent cases of tubercular spondylitis can be readily straightened, often at a single operation, and at no greater risk than is encountered in straightening similar deformities at the knee and hip.

4. In older cases of tubercular spondylitis, not yet ankylosed, but in which structural shortening has taken place in the soft parts, repeated efforts at straightening should be made in place of reducing the whole deformity at one sitting.

5. Plaster jackets are best applied with the patient in the prone horizontal posture in young children, when the deformity is below the ninth or tenth dorsal vertebra; in all other cases it is best to suspend the patient by the feet or knees. In all cases where the disease is at or above the ninth dorsal vertebra the head should be included in the plaster dressing. Pads of felt, at least three-fourths of an inch thick, should be placed on each side of the spinous processes at the region of the disease.

6. All cases should be kept recumbent for a long time, many months, after the spine has been straightened.

7. The plaster jacket and the steel brace are found to have the same faults and failings as in their use in acutely progressive cases of spondylitis that have not been subjected to forced straightening, that is to say, they can not be absolutely depended upon to prevent some degree of return of the deformity, and they may cause pressure sores.

8. The dangers from forcible correction of spinal deformities in cases of Pott's disease are tubercular meningitis and general tuberculosis from dissemination of the tubercular infection.

9. The advantages of this method of treatment are obvious: The reduction or abolition of an unsightly deformity; but no diminution of the duration of treatment over the ordinary methods by rest and immobilization is to be anticipated.

ESOPHAGOTOMY FOR THE REMOVAL OF A TOOTH PLATE IMPACTED FIVE DAYS IN THE UPPER THIRD OF THE ESOPHAGUS.

Presented to the Section on Laryngology and Otology, at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY JOHN O. ROE, M.D.

ROCHESTER, N. Y.

On Saturday, March 28, 1896, as I returned to the city after an absence of two days, I found Elisha L. Gates, a man of 66 years, impatiently awaiting me, and complaining of a difficulty in swallowing and of a severe pain in the neck.

I elicited from his attendant the following history of the trouble: On the previous Monday evening, while eating his dinner, his tooth-plate, which was an upper one, slipped into his throat and passed down into his esophagus. At the time, he choked but little and coughed only two or three times. He stated to those present that he had swallowed his plate, and in evidence called attention to a lump in his neck. The family physician was called soon after, but found no lump in his neck other than the pomum Adamii, and as he could swallow liquids without difficulty and complained of no pain in his neck, but of soreness in his abdomen, the doctor concluded that the plate had passed into his stomach.

There was no change in the patient's condition until the following Thursday night, when he began to expectorate freely. The lower portion of his throat was also somewhat painful and obstructed, but as he was still able to swallow liquids freely and the only pain complained of was in his epigastrium, it was still believed that the disturbance was caused by the tooth-plate in the stomach.

On Friday the pain in the lower part of his throat and in the neck became quite severe and he could swallow no solids whatever, and liquids in small quantities only. The family physician was again called and then concluded that the plate must be lodged in the esophagus instead of the stomach, and referred the patient to me. He came to my office, but finding that I would not return until the following day, went home and awaited my arrival, the doctor seeing nothing more of him.

On examining his throat with a sound, I found an obstruction in the upper third of the esophagus, just below the cricoid body. This was evidently the tooth plate. I then endeavored to extract it. I could readily grasp the plate with a pair of esophageal forceps, but it was so firmly fixed that the amount of force necessary to extract it would certainly have lacerated the esophagus. It was therefore deemed imprudent to attempt its extraction in this manner. I endeavored, however, to turn it up by means of an esophageal hook, but it was impossible in any manner to dislodge it. It was apparent, therefore, that esophagotomy must at once be resorted to.

I sent him to the hospital and early in the evening the operation was performed, Drs. Mulligan, W. R. Howard, Soble, Rose, and the hospital internes being present. An incision was first made in the left side of the neck, which was carefully dissected down until the esophagus was reached. An esophageal sound was then passed through the mouth and the wall raised over the tooth-plate to facilitate the incision of the esophagus. This was made in the side of the

esophagus, sufficiently long to permit the ready extraction of the tooth-plate, which was dislodged from its bed with the finger. As there was some ulceration of the esophagus where the tooth-plate had been imbedded, stitching and closure of the wound were not advisable. The esophagus and the wound were accordingly thoroughly cleansed and packed with iodoform gauze. On dressing the wound, there was found to be considerable sloughing of the inner wall of the esophagus on the side opposite to that in which the incision was made. The parts were thoroughly irrigated with antiseptic solution, by closing the esophagus below with packing and allowing the fluid to return through the wound and the mouth. Afterward this was done daily and the wound carefully packed with iodoform gauze. After the wound was cleansed pyrozone was also used, on account of its strong antiseptic properties. A solution, 1.3 grams of nitrate of silver to 30 c.c. water, was applied on cotton to the ulcerated surface for the purpose of stimulating the reparative process.

For four days the patient got on very well indeed. His temperature was increased but one degree, and he was fed regularly and freely through a gum-elastic catheter, which was placed in the esophagus with the dressing. There was no regurgitation of fluids from the stomach into the wound or through the catheter. The following Thursday morning, however, he suddenly began to feel ill, had quite a chill, with rising temperature, and grew rapidly worse. Congestion and inflammation of the lungs supervened and the old gentleman sank and died the following morning.

Tooth-plate, actual size.

A postmortem examination showed considerable sloughing of the esophagus on the side opposite to the incision, where the tooth-plate had been impacted, but there was no perforation of the wall. Both lungs were in a condition of congestion.

The history of this case previous to the accident is somewhat interesting. The tooth-plate that the old gentleman wore, which is shown in the accompanying cut, was made forty-five years before. It contained four incisor teeth, and nothing had been done to the plate until four years ago, when he accidentally dropped it, breaking off the hooks which clasped the adjoining teeth and held the plate in position. He neglected to have it repaired, and this accident was the result. He had always been well up to eleven years ago, when he had a sunstroke while working in the field. This so affected his mind that he was sent to Willard's Asylum for two years, when he fully recovered. Since that time he has been somewhat feeble-minded, and it was for this reason that his account of having swallowed his tooth plate was distrusted.

This case is of special interest also on account of the age of the patient and the rarity of the operation, and as illustrating the danger of the retention of an im-

acted sharp or angular foreign body in the esophagus for even a comparatively short period of time.

There have been reported 169 cases of esophagotomy for the removal of foreign bodies from the esophagus. The youngest patient was the case of a child one year old, operated on by Schramm¹ for the removal of a button. The child recovered. The oldest patient was a man 65 years of age, operated on by Wilson² for the removal of an impacted tooth plate. The patient died. Our patient, therefore, is the oldest case that I find recorded on which esophagotomy has been performed. Among the 169 cases, fifty-one were for the removal of impacted tooth plates, with thirty-six recoveries and fifteen deaths.

The danger attending the prolonged retention of foreign bodies in the esophagus is very great; and a large number of cases is reported in which death resulted in consequence of perforation of the esophagus, peri-esophageal and mediastinal abscesses and inflammations resulting from the retention of foreign bodies for even a very short time. The greatest danger is from rough, angular or sharp bodies that may pierce the esophagus or cause ulceration of its walls or inflammation of the surrounding parts, on account of the irritation thereby produced. In all cases, however, the rule laid down by Fischer³ is a safe one to follow. That is, if the foreign body can not be extracted within twenty-four hours, it should be removed by esophagotomy without further delay.

28 North Clinton Street.

DISCUSSION.

Dr. SCHEPPEGRELL—It is very important to make a careful examination in these cases. There are many people who suppose they have swallowed something when they have not. I had a case in which a man woke up in the night, coughing and choking, and insisted that he had swallowed his plate. At this time we had not the X-ray, and I used the esophagoscope and was able to tell him that if he had swallowed it, it had gone into the stomach. The next day his wife found the teeth in the springs of the bed. The probe is dangerous in these cases, and operation may be equally so.

Dr. L. J. HAMMOND—The mortality in cases of esophagotomy is due to the fact that the posterior mediastinum has been entered, as shown by the postmortem. Esophagotomy is the more desirable because the probe is likely to enter the mediastinum. Esophagotomy enables us to find the point through the tube and not disturb the ulcerated region.

Dr. ROE—A number of cases of imaginary swallowing of the teeth have been reported. In one case the patient, a man, had nausea and vomiting, until his teeth were found under the bed, when all these distressing symptoms at once disappeared.

In regard to the esophagoscope for examining the interior of the esophagus, Mackenzie has devised one which is depicted in his work on "Diseases of the Throat." One has also been invented by Leuer of Vienna. With the latter instrument, by the use of an electric light attached, we are enabled to see into the stomach also.

A NEW METHOD OF SKIN GRAFTING.

Read at the Eighth Annual Meeting of the Washington State Medical Society, held at Spokane, May 11 and 12, 1897.

BY GEORGE T. DOOLITTLE, M.D.

SPOKANE, WASH.

There are few minor operations so annoying or troublesome as to undertake to cover a large denuded surface with skin. The average practitioner attempts to obtain large grafts by the use of the razor, but generally after one or two trials he abandons the effort in disgust. In fact, it requires an expert to do it successfully.

Many cases of extensive sores and granulating sur-

¹ Wiener medizinische Wochenschrift, 1895, XLV, 2102-2106.

² Liverpool Medical and Chirurgical Journal, July, 1894, p. 480.

³ Deutsche Zeitschrift f. Chirurgie, Leipzig, 1888-89, Bd. xxix, S. 110.

faces from burns and other causes are left to heal over as best they may, aided only by an antiseptic dressing, to be followed by the inevitable result of ugly scars and generally more or less contraction.

The old method of using small grafts made it a very slow process to cover a denuded surface of any considerable size, and the varied thickness of the grafts made growth uncertain. Larger pieces were tried but failure often followed, until Thiersch introduced his method, which consisted in antiseptically preparing the skin to be taken; also the surface to be grafted upon, and using a razor to cut the strips of skin.

The objection to this method is the difficulty in making an even cut, when using a knife or razor. To facilitate the cutting, Dr. McBurney, of New York, uses a pair of short toothed retractors to fasten into the skin and hold it taut while cutting. Even with the aid of these hooks, which few physicians have, the operation is not easy, and the difficulty of skin grafting, the cutting of large pieces of skin of even thickness, is not removed.

A formidable case was presented to me, recently, of an adult, where there was total loss of skin on one leg from ankle to knee, including a surface of about seventy-five square inches. This condition was caused by a bruise and sore, starting about eight years ago, going from bad to worse, with indifferent results as to treatment. No history of any constitutional disease.

It was a question if amputation would not give the best results. I was called in with that object in view by the patient's friends, and we considered the probable contractions that would result from the usual method of skin grafting, as there was already some contraction in the popliteal space, which together with the sore, made the limb useless.

We decided to do skin grafting and use the safety razor to cut the grafts with. The first attempt was successful, and we were able to make grafts one and a half by two and a-half inches and of an even thickness. Later, we made large cuts, one and a half by five inches, the large growing as readily as the small, with the advantage that the larger the grafts the less secretion from the granular surface. The advantage of the safety razor, over the knife or common razor, was marked by the quickness and ease with which these sections were obtained. The skin from which the grafts were taken was first shaved, so the hair would not increase the liability of the grafts to stick to the dressing, then scrubbed with green soap and water and washed over with ether or alcohol.

A few words are necessary in regard to the razor. (The Star made the best cuts.) Set the blade forward to about the edge of the guard. Grasp the razor between the thumb and first and second finger, thumb at the front of the razor and the first and second finger pressed firmly against the back of the blade to keep it from slipping. With the left hand hold the skin tight just back of where you begin to cut; hold the blade at an angle of about 45 degrees with the skin surface; cut toward you and against the grain; don't be afraid to bear down until you feel the blade taking hold of the skin, which will roll up on the blade as it is cut. After a little practice a strip six or eight inches long can be cut if necessary. Remove the blade and the skin will be found gathered up and the upper surface ready to spread, which is done by placing the blade flat on the granulations, holding down the last cut edge of the skin with some light instrument, and withdrawing the blade. The skin will readily spread evenly over the granular surface.

In this case there was no preparatory treatment by scraping the granulations in order to freshen them. The surface was simply washed with 1 to 3000 bichlorid solution and then rinsed with boiled water.

In dressing the planted grafts, a liberal supply of moist bichlorid gauze was used and the part firmly bandaged, without protective. Fresh gauze was applied every day and seldom was any trouble experienced from its sticking to the grafts, if a little care was used. About every third day more grafts were applied.

There was so large a surface to cover that it was thought best to leave small interspaces between grafts and thereby hasten the covering; but if these had not been left, the leg would have been covered and the patient discharged in half the time, as the vitality in the leg was not sufficient for rapid growth of the grafts and filling up of the spaces.

Today the leg is completely covered with skin with no contraction at the knee. The patient is discharged and is able to do her work.

SUMMARY.

1. With the use of the safety razor any physician can easily obtain large uniform grafts.

2. By the use of large grafts we have little or no contraction of tissue and the work of covering a large denuded surface is greatly hastened.

3. Where there is a granular surface without ulceration it is not necessary, in preparatory treatment, to freshen the granulations by scraping; neither is a protective necessary in dressing the surface, it only sweats and softens the grafts.

Rookery Building.

EUSTRONGYLUS GIGAS.

BY G. W. MOREHOUSE, M.D.

SPARTA, OHIO.

John Hopkins of Centerburg, Ohio, age 58, weight 175 pounds, medium height, general health good. March 10, 1896, had an attack of severe renal colic on right side. He passed from his bladder, according to his own statement, a pint of blood during the first twenty-four hours. He had eight similar attacks during the month of March. Attending physicians at first diagnosed renal calculus.

March 27, he passed from the urethra a worm nearly a foot in length. Two more worms, four and seven inches long, respectively, were passed by April 1. Since this date, he states that he has expelled from his bladder fifty-five worms, from one inch to one foot long, with the addition of numerous flesh-like shreds, which he considers portions of additional worms, but which were probably blood coagula. He has not bled much since passing the first worm. He claims now to pass the parasites with comparative ease. I have seen a number of the worms and can vouch for them as answering in every detail the description given by writers.

Uranalysis, from a specimen voided in my presence, Aug. 22, 1897, showed specific gravity 1018, reaction acid, color light yellow, turbidity slight, and traces of albumin.

Microscopically, blood cells, scattered pus cells, pelvic epithelium and numerous circular nucleated bodies, about one-third the size of red corpuscles.

The paucity of literature on this subject is commensurate with the rarity of the disease. Dr. Samuel D. Gross, in his "Surgery," fourth edition, Vol. 2, p.

653, gives a good description of the parasite, but mentions no cases.

Dr. Austin Flint, in fourth edition on "Practice," merely mentions the name of the worm as "*strongylus gigas*, inhabiting the kidneys."

Niemeyer, 1874, Vol. 2, p. 47, gives a very good description, but cites no cases. He states that the worm is from six inches to three feet in length.

In Quain's "Dictionary of Medicine," 1885, p. 1554, it is stated that the "*eustrongylus gigas* has only been once found in the human body," and that "the specimen is still preserved in the museum of the Royal College of Surgeons."

In Pepper's "System of Medicine," 1886, Vol. 4, p. 66, it is mentioned as occurring in seven different cases, but that "only part of these are admitted as genuine by certain authors."

The case cited by the writer will be kept under observation and reported upon as to future developments.

REMOVAL OF THE OSSICLES, WITH REPORT OF SIX CASES.

BY NORVAL H. PIERCE, M.D.

Professor of Otology in Post-Graduate Medical School and Hospital; Surgeon to Throat, Nose and Ear Department of the Michael Reese Hospital and Dispensary; Laryngologist and Rhinologist to Emergency Hospital.
CHICAGO, ILL.

Case 1.—Chronic sclerosing inflammation of the middle ear. J. B., a negro, age 25, employed as a waiter. His general condition is good, but there is a rheumatic diathesis. His previous history is of but little value. Has had little or no treatment. Has steadily increasing deafness which became apparent in the left ear first, about three years previously. This has become so great that it seriously interferes with the proper performance of his vocation. There is arterial tinnitus but he complained of it only when questioned. There has been no pain: no discharge. The deafness has become decidedly worse during the preceding four months.

Auricles and external canals normal, except for the absence of cerumen in the latter. Tympanic membranes pale; mobility slightly decreased; not depressed. Light reflexes quite normal. Handles of mallei were defined through their entire lengths. The Eustachian tube only slightly occluded; that on the right side more so than on the left.

Weber test positive for the right ear. Rinne with Koenig's A, negative for both; C, negative in right.

Speech for right ear two feet; for left between three and four. Whisper occasionally understood in left at one inch. Right not heard. Watch barely heard on firm pressure in left. Deafness in right ear by aerial conduction for tuning forks up to C¹, and duration markedly diminished. Left ear C¹ could be heard on some days. Nose and naso-pharynx negative.

Nov. 10, 1893, I operated on the right ear, with cocaine for local anesthesia. The drumhead and malleus and incus were removed. The stapes was found to be partially fixed in the pelvis of the fenestra. It was mobilized by severing the tissue about the footplate and left in situ.

Immediately after the operation, watch could be heard on light pressure. Speech four feet, but the patient complained of hearing in a confused manner. There was no reaction. The corda tympani had been severed and a metallic taste, on the corresponding side of the tongue, was complained of, but this disappeared in less than a week. The tinnitus was markedly benefited. After three months, speech was heard in the ear operated on, two feet; watch barely on firm pressure, and the tinnitus had recurred but not continuously.

Case 2.—Chronic sclerosing inflammation of middle ear. C. E., female; German; age 68; married. Complained principally of tinnitus. One had to shout into the ears to have her understood. Lucæ's hammer-fork of 2048 vibrations could be heard in the right ear, by aerial conduction, when held very close. But it was in the right ear that the tinnitus was greatest. She applied for relief for this distressing symptom, and not to regain hearing. She described the noise as a great roaring sound. I chose the right ear for an operation because the noise in that ear was greatest. I removed the tympanic membrane, malleus and incus. The stapes was immovably

fixed in the fenestra. In attempting to remove it, the crura broke off near the footplate. Subsequent examination proved that the crura were atrophied—a condition, noted by Schwartz and Blake of Boston, which is liable to occur in stapes which have been ankylosed. There were apparently no adhesion bands, nor ankylosis other than that of the stapes in the pelvis.

Immediately after the operation the tinnitus was slightly relieved, but in a week it was as bad as ever.

Case 3.—Chronic suppuration of the middle ear. A. F. T., American; male; age 25; clerk. Is of full habit. The disease dates from his thirteenth year, when he had scarlet fever. The discharge in the right ear ceased years ago, but that in the left continued. This was not great but very foul, and subject to exacerbations, accompanied with pain. Hearing for the watch three inches; for speech four feet; for whisper less than a foot. Drumhead thickened markedly; a central perforation through which projects granulation tissue, imbedded in which may be felt the necrosed remains of the upper portion of the handle of the malleus.

Nov. 9, 1894, I removed the drumhead, malleus and incus. The hemorrhage from the granulation tissue was abundant. The tympanic cavity, including the attic, was scraped clean and the whole packed with iodoform gauze. On the following day the packing was removed and the tympanum irrigated with permanganate of potassium solution, 1-1200, and again packed. Whenever exuberant granulations appeared, they were removed with the sharp spoon, and the bases cauterized with chromic acid in substance. With this treatment the discharge ceased in less than two months. Hearing unimproved. The arterial tinnitus was, however, greatly decreased.

Case 4.—Chronic suppuration of middle ear. R. S., American; age 24; male; machinist. Suppuration existed since his fifth year, as a sequela of scarlet fever. Condition about the same as the foregoing case, excepting that the membrane was more thickened, the discharge more offensive, and the perforation smaller and situated higher up in the posterior-superior quadrant.

Dec. 23, 1894, the membrane and body of the malleus was removed. Hemorrhage was profuse, delaying the operation greatly. I could not find the incus. The attic was freed from granulation tissue as far as possible, but on account of hemorrhage, the spoon was not used as freely as it otherwise would have been. The cavity was irrigated with Hartman's canula and packed. There was no reaction. The patient left his bed on the following day. In ten weeks, although there was still some oozing, not altogether odorless, he considered himself well enough to accept a position in a distant city, and went from under my observation. In this case the hearing was improved; five inches for watch, and three feet for speech.

Case 5.—Chronic catarrh of the middle ear. S. S. E., American; male; age 33; farmer. Deafness lasting seven years. Slowly progressive. Has had no previous treatment. General history negative, with the exception that he dates his tinnitus from an attack of malaria. There has been no discharge; little or no pain. Tinnitus continuous.

Both tympanic membranes depressed; darkened; handles shortened. Short processes prominent. Tympanic membrane and malleus of left ear movable. Weber to left. Positive Rinne for right; negative for left ear, with Koenig's A fork. Eustachian tubes slightly pervious. Speech for right ear three feet; whisper six inches; tuning fork C₁ heard; watch two inches. Left ear, speech one foot; whisper one inch; watch on firm pressure.

Operation, Feb. 10, 1894. Left ear. Membrane more thickened than I supposed before cutting it. The tensor tympani snapped when cut. The malleus and incus removed. The stapes was quite movable and was allowed to remain. Improvement after operation marked; for speech three feet; for whisper nearly a foot; watch three inches.

Although the tympanic membrane had partially reformed the improvement remained the same eight months afterward.

Case 6.—Chronic sclerosing inflammation of the middle ear. A. E.; female; age 41. She is now in the menopause. She has had ear trouble five years. The tinnitus is continuous and produces intolerable nervousness. She is becoming worse rapidly. There is no history of heredity.

Examination: Auricles, normal; external auditory canals normal and contain a very dark-colored wax. Tympanic membranes lack luster, and the left is somewhat retracted. Eustachian tubes are both open. Voice tests gave for right ear: speech at two feet; whisper on contact; watch not on firm pressure. For the left ear: speech at two feet; whisper at two inches; watch on forced pressure; fork C_{III} heard in left ear; C_{II} in the right; Weber to the left. Galton heard in the left ear in the upper half of its register only. I removed the drumhead, malleus and incus of the left ear under cocaine.

The stapes was found to be firmly fixed in the window and could not be removed without endangering fracture of the crura. The results were nil.

REMARKS.

Here we have six cases where the tympanic membrane and one or more of the ossicles were removed. Two of them were for chronic suppuration, three for sclerosis, and one for chronic catarrh. In the suppurative cases the results were highly satisfactory. In one case after a duration of twelve years the suppuration ceased in two months. In the other, after a duration of nineteen years, the ear was practically dry in ten weeks. We are not justified, however, in expecting that all cases will have so happy a termination. I have lately had a case under my care which was operated on by an eminent otologist over a year and a half previously, and the suppuration, foul and abundant, continued up to a few weeks ago. In this case the membrane had not reformed in the least. The pus seemed to arise from a point at the superior posterior portion of the cavity. Here I detected superficial caries. After carefully scraping the diseased area and packing with iodoform gauze for a short period, the suppuration ceased entirely. But there is a slight relapse whenever the patient takes cold. These relapses do not last but a day or two, and readily yield to cleansing douches. I believe that such relapses will occur until the cavity has been epidermized. The loss of the tympanic membrane may account for the condition, the mucous membrane being exposed to every infection from the air via the external auditory canal.

All this, however, does not militate against the performance of the operation in chronic suppurative otitis. I do not coincide with the opinion that this operation should be performed at an early date. There is a danger in being too precipitate, and yet there are a certain number of cases which very early in their course indicate this procedure. For instance, where there is a large perforation with no necrosis or granulation that may be demonstrated, but where a copious, constant or intermittent foul smelling discharge is present. All are aware of the futility of treating by the ordinary methods those cases in which fistulous perforations occur primarily in the membrana flaccida, for in such cases there is usually caries of the malleus or incus, or both.

Schwartzze regards as nearly pathognomonic of caries of the head of the malleus a perforation over the short process of the malleus, with or without the presence of granulations. Further experience has fully verified this conclusion since its first publication (1884).

Grunert (A. F. O. xxxiii, p. 207), gives the following otoscopic picture as aiding in the diagnosis of incus caries:

1. Defect in the extreme upper portion of the tympanic membrane through which can be seen the retracted malleus. Beneath the upper and posterior edge of the perforated membrane may be seen a small granulation, or after careful irrigation a small drop of pus remaining, coming from above and behind. (Caries of the long process of the incus.)
2. Perforation behind the malleus, extending above to the edge of the membrana Shrapnelli, and forward quite or nearly to the long process of the malleus. (Caries of the long process of the incus.)
3. Fistula in the membrana Shrapnelli behind the processus brevis of the malleus. (Isolated caries of the incus.)

When there are two fistulous openings above and behind the processus brevis, or when the entire membrana flaccida is replaced by broad granulations the co-existence of caries of both the incus and the head of the malleus is in the highest degree probable.

Ludewig states the frequency of occurrence of isolated malleus caries compared with isolated incus caries as six to ten. The predilection point for caries of the ossicles is the long process of the incus (72 per cent). This is explained by its position, lying as it does, free in the tympanum. Its nourishment can be much more easily interfered with than that of the long process of the malleus, the circulation of which is intimately connected with the vessels of the tympanic membrane. Years ago, Schwartzze called attention to this point in connection with that peculiar destructive process of the long process of the incus, accompanied by the accumulation of pus which undergoes fatty degeneration within the cavum, the tympanic membrane not being perforated.

The next in frequency to become carious is the body of the incus, 46 per cent. The head of the malleus was the seat of caries in 23 per cent., the handle in 25, and the neck 14, and the joint surface of the head 7 per cent.

Schwartzze gives the following conclusion, based on the condition of the ossicles in a series of cases, the tympanic cavities of which were laid bare by external operation:

1. The amboss becomes earlier and more frequently carious than the hammer.
2. Isolated caries of the amboss occurs more frequently than isolated caries of the hammer.
3. In isolated caries of the incus, the incudo-malleus joint is unaffected.
4. The long process of the incus is by far the most often carious.
5. The incus is frequently destroyed in toto, even when the malleus in whole or in part is still present. I have formulated the following

INDICATIONS FOR OPERATION:

1. When the perforations, situated anywhere in the pars tensa, is small and the membrane thickened and the discharge copious, pustular, long continued and offensive and has resisted continuous treatment by means of gauze drain for one month.
2. Where the perforation is small, the membrane thickened, the discharge scanty, but odorous.
3. Where more or less of the pars tensa has been lost; but the discharge continues, evidently coming from the attic.
4. When any of the indications as formulated by Schwartzze or Grunert are present (see supra).

When we determine upon the removal of the ossicles for the cure of suppurative otitis, the effect which that procedure may have upon the hearing scarcely enters into consideration, for the removal of a suppurating focus in the locality is much more important than the preservation of audition. But we may hope, not only that the same degree of hearing may exist after the operation as before, but that it may be increased. Ludewig in analysing the cases operated upon in Schwartzze's clinic, to the end of 1891, found that in half the cases the hearing was markedly increased; unchanged in about one-third, and decreased in about one-twelfth. In Jack's eleven cases, all were improved in hearing power.

There still remains the consideration of this opera-

tion in its relation to catarrhal and sclerosing diseases of the middle ear. That it is indicated in certain cases belonging to the former class is at this time assured, but the good name of the operation and the operator forbid its use in the latter class.

Those cases of deafness which are caused by anchylosis of the stapes in the pelvis of the fenestra ovalis will not be relieved or improved by the removal of the incus, hammer or tympanic membrane. When, however, the fixity of the stapes is secondary to adhesions between other portions of the cavum and its contents, the removal of those adhesions will more or less improve audition. Likewise when the sound waves are reflected from the scala by adhesions or anchylosis which render the malleus and incus more or less immobile, the removal of the bones will be beneficial. But it is in sclerosis otitis that stapes anchylosis occurs earliest and most surely; this is the chief characteristic of the process, the real nature of which is almost entirely unknown to us. It is probable that the portion of the pelvis immediately surrounding the footplate is where the sclerosing process begins, and from this point spreads to the structures of the internal as well as to those of the middle ear. Operative interference for the relief of deafness or subjective sensations in these cases can be attended only with disappointment.

In the purely catarrhal cases the operation is rational and promises relief to subjective sensation and improvement of audition.

OSSICULOTOMY IN CHRONIC SUPPUR- ATION OF MIDDLE EAR.

Presented in the Section on Laryngology and Otology, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY J. A. STUCKY, M.D.

LEXINGTON, KY.

In chronic suppuration of the middle ear where there is necrosis of the soft tissues, tympanic walls and attic, and caries of one or both ossicles, the most rational treatment consists in removing the carious ossicles and all necrosed granular and fibrous tissue in the tympanic cavity.

Ossiculotomy for caries has passed the experimental stage and is now recognized not only as justifiable, but a rational method of treatment. There being no such thing as special surgery, we are no more justified in leaving carious bone in the middle ear than is the general surgeon in leaving it in any other portion of the body accessible to removal. The same general and well-known principles of surgery which apply to caries and necrosis of other parts of the body, are equally applicable to the ear, and when we find carious ossicles and necrosed tympanic walls they should be removed and all necrosed parts thoroughly curetted. There still exists some prejudice against this operation which is hard to understand. I can see no reason for tolerating the presence of dead bone in the tympanic cavity, neither do I believe it possible to cure a suppuration as long as the carious and infectious matter remains. From the results obtained in the thirty-six cases in which I removed one or both ossicles (malleus and incus) and curetted the attic, I am convinced that ossiculotomy (where caries exists) is not only the most conservative, but the most rational treatment for the majority of cases of chronic suppuration of the middle ear. The cases included in this report have been operated upon within the

last two years, the latest included in the report was operated upon four months ago.

The object to be attained is the complete removal of carious bone and the thorough curettement of the necrosed and granular tissue, and the establishment of perfect drainage of the attic and lower tympanic cavity. This I believe can be successfully done through the auditory canal. I follow the plan outlined by Dr. E. B. Dench of New York in his textbook on "Diseases of the Ear," except that I substitute a modification of Sexton's curette for cleansing the attic and removing part of the tympanic ring and superior wall of the auditory canal. So much has been written by eminent men, both in America and Europe, on this subject that a description of the operation is not necessary.

Observation leads me to agree with the published statement of Dr. C. H. Burnett that "necrotic tympanic structures must be removed before chronic purulency can be checked." I also believe that the Stacke or rational operation could be obviated in many cases if the entire tympanic cavity was thoroughly cleansed, and free and uninterrupted drainage through the auditory canal established. I need scarcely mention in this connection that the nasal and pharyngo-nasal cavities should receive scrupulous attention, in order that there be no obstruction to nasal respiration or danger of re-infection of the tympanic cavity through the Eustachian tube. From published reports I infer that secondary operations for relief of middle ear suppuration are as frequent from the Stacke operation as from those through the canal. The after-treatment is much shorter, there is no external wound, hence no scar, and less danger of injury to the facial nerve. I think the operation of ossiculotomy in the class of cases under consideration should be done under general anesthesia. I have found it impossible to do it with cocaine, the scraping of the wall of the tympanum causing intense pain. The after-treatment consists of cleansing and facilitating drainage by use of narrow strips of gauze introduced well into the cavity.

In one of the thirty-six cases included in this report there was facial paralysis (motor) which came on the day before and lasted for five weeks after the operation. There was an extensive caries of the ossicles and I suppose the paralysis was brought on by an exacerbation of the trouble due to an acute otitis, producing a thickening of its sheath.

A summary of the results in cases operated upon are as follows: In thirty cases suppuration ceased and hearing was improved from 10 to 20 per cent.; all uneasiness in ear and head relieved. In four cases the suppuration stopped entirely for several months, then returned; this was due to formation of granulations, which were easily destroyed and patient relieved; no improvement in hearing. In two cases the results were negative, so far as relief of suppuration or improvement of hearing; the fulness and dizziness were relieved and suppuration lessened. These cases were afterward found to be tubercular. In eleven cases the incus could not be found and only a part of the malleus. In the remaining twenty-five cases the entire remaining portions of the malleus and incus were removed. In no case did I find only one ossicle involved, the greatest amount of necrosis being observed in the incus.

The chief points to be observed in this method of treatment are: *a*, remove all carious bone; *b*, cleanse

thoroughly the attic and tympanic cavity; c, establish free drainage.

The results obtained in the thirty-six cases referred to in this report are: 1, cessation of the discharge; 2, relief of the fulness, dizziness and general uneasiness complained of; 3, slight to marked improvement in the hearing; 4, great improvement in general health.

DISCUSSION ON PAPERS OF DRS. BURNETT AND STUCKY.

Dr. BURNETT—I have made an omission. I have failed to make any remark about the stapes, but in no case have I ever thought of removing this bone. For, to do this is simply opening the door and inviting the pus to enter the cranial cavity.

Dr. GLEASON—In how many of these cases was caries of the ossicles still active? It seems probable that in many of them the process ceased after partial destruction of a bonelet, and that some other cause was responsible for the continuation of the discharge for years. Whatever operation is done, chronic otitis media is never completely cured and that almost invariably there will be a recurrence of the discharge if the case be entirely neglected. The discharge tends to recur whether the operation consist in the mere removal of the malleus and incus, the removal of the ossicles and the lateral wall of the attic, or the most complete and radical Stacke operation. In a large proportion of cases it is possible to bring about a cure, or rather a cessation of discharge without operative interference so far as the ossicles are concerned. Frequent and thorough intra-tympanic syringing will in some cases bring about a cessation of the discharge. In other cases it is necessary to remove the ossicles to gain access to the attic for treatment. Still better access can be obtained by curetting away through the canal the lateral wall of the attic; but no matter what the operation be the irritation caused by the presence of dust, exfoliated epidermis and other substances that accumulate in the middle ear when the drumhead is lacking will, unless they are removed from time to time, in the course of months or years bring about a recurrence of the discharge. After the discharge has ceased the ear is in the same condition as the teeth after the dentist has filled them and is through with his patient for the time at least.

Dr. MAX THORNER There can be no doubt that where we have caries and necrosis it must be removed. We did not recognize this until the general surgeons called our attention to it. We must proceed on surgical principles. If we have caries of the ossicles alone, we can remove the caries by removing the ossicles. I have operated on a number of such cases, and have seen good results occasionally in cases operated exclusively by ossiculectomy. But in most cases the caries is not limited to the ossicle. The attic and the antrum communicate by a narrow opening. I compare this narrow channel, the so called aditus ad antrum, to an hour-glass contraction. Through this narrow channel caries extends into the antrum. If in such cases we do a mastoid operation we will be astonished at the condition that we find. I have seen cases where the mastoid cells were honeycombed with granulations, while externally nothing indicated such a condition. Such cases can not be cured by ossiculectomy. If we remove first the ossicles and after a reasonable time no improvement follows, a more radical operation may be done. But many patients will not submit to this. I would limit the indications for ossiculectomy to those cases in which we have good reason to believe that only the ossicles are affected, or in which we do it for the purpose of procuring better drainage from the attic.

Dr. Gleason thinks that these cases can not be entirely cured. If he refers to the cases which are operated upon by ossiculectomy, I think he is right in regard to a number of cases, which will later on have recurrences. For we can not get rid of all the carious portions if caries is extensive in the attic and antrum, but in the more radical operation, by opening the antrum widely we can remove all the carious portions and can graft skin into the cavity and by doing that can and do get a cure. I think that from two to three years are sufficient to judge results. I, and many others before me, have had a number of cases which remained cured. I would not say that every case must have the radical operation, for I favor ossiculectomy. But it is difficult to say when the ossicles only are affected, and the cases have to be carefully selected for this operation.

Dr. J. A. STUCKY—I do not want to touch the stapes if I can help it. I never remove it. I did so once, but it was accidental. As to what Dr. Gleason said about the activity of the caries, in most of my cases it was still active. The secret of success in these cases is the establishment of free drainage. I

I have not found the intra-tympanic syringe a success. I have always treated cases for some time before removing the ossicles. As to a cure, I think if a case remains free from symptoms, discharge, etc., for four or five months we may call it cured. I saw some cases recently on which I operated two years ago, and there has been no discharge or trouble since three or four weeks after operation. I consider them cured.

Dr. BURNETT—I have always thought caries in the ossicles was active. No very scientific answer could be given without using the microscope. My experience has been that caries was limited to the ossicles. I think we can say positively that it is, if cure takes place speedily. If cure takes place slowly, we may know that there was denudation of the walls of the tympanic cavity. I have generally found some denudation, but I do not consider that as very significant, and by no means a justification of curettement. I know of cases of chronic purulent discharge of the ear which would have been cured by the removal of the ossicles if the curette had not been used. We get by this operation chiefly improved drainage, as well as the removal of the septic nidus. As to Dr. Thorner's remark about knowing when the ossicles are affected, I would say we do not know exactly what is going on in the antrum or in the mastoid cells, in an ordinary case of otorrhea with suppuration. I regard the antrum as a part of the middle ear. After ossiculectomy in these purulent cases, if we get a cure we may conclude that the antrum was not much diseased, if at all. When the antrum is diseased I have seen good results from free drainage and even if there is some relapse the improved drainage enables the patient to get rid of the fresh products of suppuration and thus escape septicemia. If we are not sure that the mastoid cavity is diseased, I do not think we should perform a Stacke operation and attack the disease through the mastoid cortex. Attack the disease in the simpler way first, through the meatus.

A FEW PARAGRAPHS ABOUT TOBACCO AMBLYOPIA.

BY WILLIAM B. MEANY, M.D.

MEMBER OF THE AMERICAN MEDICAL ASSOCIATION, ETC.
LOUISVILLE, KY.

It is hard to say why tobacco has been selected as the general agent for inciting what is called toxic amblyopia. Is it not a fact that various toxic agents are said to be attended by varying degrees of amblyopia, and that some writers, apparently eager to ignore the effects of alcohol, have taken up the consideration of central and peripheral lesions of the optic nerve, clearly due to prolonged local disturbances of the vasomotor system, from various kinds of excesses and mechanical obstruction to nutrition, even including tuberculosis, to set forth an exaggerated view of the by no means well-established toxic effect of tobacco?

In Turkey where tobacco is inordinately used by both sexes and among all classes, the so-called tobacco amblyopia, according to competent observers, is almost unknown, and yet the daily consumption of tobacco by this portion of the Mussulmanic race is enormous. Carefully made assays show that the smoke from Turkish cigarettes (which the Turk draws directly into the lungs) contains about double the percentage of nicotine as is found in cigars made from Havana tobacco. Does not the Moslemic law religiously interdict, among other things, the use of alcohol in any form, and exacts from the faithful strict observance of bodily cleanliness by morning and evening ablutions?

In a series of clinical observations the writer reported to the Kentucky State Medical Society, in June, 1895, there will be found some cases in which it was clearly apparent that amblyopia was not caused by tobacco, but was due directly to retrobulbar neuritis. Similar cases clearly establish the fact that symmetrical scotomata is neither diagnostic of tobacco

amblyopia nor constantly present in otherwise apparently "well-established cases."

In one case the central scotoma was decidedly asymmetrical; ophthalmoscopic signs *nil*; the fields for white good, but there was a scotoma for red and green extending from the fixation point to beyond the blind spot, and about 15 degrees upward and downward; inside this area he called red yellow and green white; outside of it he recognized color well. There was no scotoma for blue: he had frequent attacks of what he called nervousness; knee reflexes normal; has neither albumin nor sugar in urine, specific gravity 1022. No specific history. The patient admits being a regular drinker and smoker. Mercury, iron and nux vomica, with strict attention to bodily cleanliness, by frequent bathings, outdoor exercise by walking, in conjunction with a wholesome diet, brought about a complete cure. Alcoholic stimulants were strictly proscribed, but smoking, however, upon admission of the patient, was not discontinued. Is there a physician who at some time in his medical career has not been taught that the "exact symmetry of this affection is one of its marked features"; does one "always find the same amount of defect in each eye," and achromatopsic phenomena fairly attributed to tobacco alone?

Are these scotomata for certain colors due to toxic influences or structural changes?

We are aware, however, that occasionally a slight deviation between the two eyes coexists, which is accounted for by an original difference in visual acuity.

A brief inquiry into the anatomic conditions in the disease described, affecting the fundi, optic discs and their contiguous intracranial connections appears to be pertinent. The optic nerves have their origin in the thalami optici and the corpora quadrigemina, receiving filaments from the corpora geniculata, with filaments from the corpora geniculata, tuber cinereum, lamina cinerea, the anterior perforated space, the gray substance of the brain, the posterior columns of the spinal cord; the optic apparatus being a series of projections—the first the retina, a secondary projection in the cortex of the occipital lobe or, as some will have it, in the angular gyrus.

Is it unreasonable for one to be more inclined, taking into consideration environments and the "eccentric" character of patients, who are said to especially suffer from this form of amblyopia, to favor some mechanical obstruction to nutrition, inflammation excited by tuberculosis or even circulatory or vasomotor disturbances, the reflex phenomena in cases of megrim, keeping well to the front the neurologic elements, as some of these factors appear to be in a degree present in most all the forms of amblyopia, and not make tobacco alone chargeable for certain undeveloped or over-exaggerated type of amaurosis?

A shock to the nervous system from a railroad accident has been said to be followed by the so-called tobacco amblyopic indications. That a peculiar form of white atrophy of the optic nerve, distinguished by some ophthalmologists as having a peculiar haziness surrounding the edges of the discs, and by others without this effusion or blurring of the outlines, and attributed to the use of tobacco, should from this variance call for explicit explanation. How difficult, then, it is to differentiate the varying forms and degrees of amblyopia must appear to the clinical observer.

Does not the present limited knowledge of the rela-

tions of those aspects of the fundus of the eyes, to what is concurrently going on in the optic avenues and their several contiguous portions of the complex double brain and spinal cord, prove to us how rudimentary must be our insight into this important field of inquiry?

When we take into consideration the study of the brain function—employing that term in its widest sense—and of the aberration occurring in it, that we call disease, we can see that the subject is still in its very infancy. Can we so readily differentiate the varying forms of amblyopia, and not be "startled" when we hear it stated or see it set forth in writing describing certain trophic neuroses that are unmistakably distinctive types of disease—as "characteristic effects" of the use of tobacco?

What physician in the school of ophthalmology, no matter how enlarged his experience or favorable the surroundings to the proper study of the aberrations found in eye troubles, may say he is safe in the recognition and differentiation of anesthetic retinitis, coincident with locomotor ataxy, the retinitis of anemia and the multifarious forms of toxemia along with tobacco amblyopia—for is it not a fact that in the majority of instances we are unable with assurance to assign a cause? In lead poisoning, for instance, is the central visual disturbance due to saturnine cachexia or to albuminuria, anesthetic paralysis and encephalopathy which is so often present?

All the conspicuous symptoms of tobacco amblyopia are, in a great measure, identical with those visual disturbances which arise from axial neuritis, observed in poisoning by sulphur, bisulphid of carbon, stramonium, cannabis indica, iodoform, quinin, alcohol and even from starvation itself.

Is it not a fact that similar lesions and visual disturbances exist in varying degrees, more or less prominent, in nearly all organic lesions of the brain and spinal cord; in embolism, loss of blood, dementia paralytica, traumatism, syphilis, tuberculosis, epilepsy, dysmenorrhea; various forms of nephritis, miasmatic fevers, anemia, rheumatism, podagra and la grippe?

The very fact that a number of cases of so-called tobacco amblyopia get well, although the smoking is kept up, casts doubt upon the diagnosis. Medicinal agents which correct local lesions, and morbid conditions of the system generally, are unquestionably in evidence as the means of mitigating the disease and bringing about a cure in even old standing chronic cases. Is it fair to assume therefore that the so-called tobacco amblyopia has any distinctive characteristics? Tobacco amblyopia may have a possible existence, but closer study must show the difficulty of discriminating as to the cause, and absence of positive proofs must be admitted in a majority of cases.

In the *New York Medical Journal* of Dec. 18, 1897, there appears under caption of "Tobacco Amblyopia in a Horse," an abstract of the proceedings of a meeting of the section in ophthalmology, of the College of Physicians of Philadelphia, wherein a description is set forth of a form of amblyopia in horses, which was attributed to their eating the Australian tobacco plant. A pronounced advocate of "tobacco amblyopia" exhibited to the section two slides which a Melbourne (Australia) physician had prepared from the optic nerves of a horse which had become blind. One of these originally stained sections was restained with carmin, according to the Weigert method, and

was said to show distinct signs of disease, and described as one of progressing fibrosis with degeneration (atrophy) of the nerve fibers. Is there a pathologic anatomist of today who can so readily differentiate the varying types of nerve lesions and say that this abnormal degeneration (a species of fibrosis) is diagnostic of the toxic effect of tobacco alone, either in the optic nerves of the human being or in Australian equines which are constrained to the use of tobacco?

Why go to Australia where "unexpected happenings" occur in the "make-up" of the creatures classed or unclassified among the animal kingdom?

The habit of smoking is now probably at its apogee, certainly it would be difficult to give it a wider scope of action. It may be taken as a rule that every man smokes, who by idiosyncrasy is not disabled from indulgence. They who scorn the "filthy habit" and are disposed to attribute many ills to its use, belong to two or possibly three categories, whose classification need not be detailed here.

It may be prudent to mildly infer that some reasoning from their anti-tobacco standpoint, in assuming that the "weed" is responsible for a certain form of amblyopia, and, in their haste to satisfy themselves with a cursory examination, even to the ignoring of the physiologic aspect and, to further their reasoning in contra-distinction to anatomic facts, are sacrificing themselves on the altar of duty rather than promoting their purposes.

THE VENOUS CHANNELS OF THE AURAL REGION.

Presented to the Section on Laryngology and Otology at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY B. ALEXANDER RANDALL, M.A., M.D.

PROFESSOR OF EAR-DISEASES UNIVERSITY OF PENNSYLVANIA AND
PHILADELPHIA POLYCLINIC, ETC.
PHILADELPHIA, PA.

Study of the venous channels of the head had no great interest for most aural surgeons until a comparatively recent period; for, their important relations to septic processes in the ear and throughout the body were known and appreciated by few. Many knew that the sigmoid sinus lay uncomfortably near to their field of operation in opening the mastoid, and gave their attention largely to its avoidance. Latterly, among general surgeons especially, there has been rather a swing in the opposite direction in their readiness, on slight occasion, to expose and explore this sinus and take other liberties which better judgement and more diagnostic acumen would have showed them to be needless. Important as is this channel, it is far from being the only one demanding thoughtful consideration in a case of otitic pyemia.

The position and relation of the great sinuses of the brain need not detain us, for it is fairly appreciated that the lateral sinus is the continuation of the superior longitudinal and straight sinuses and follows the inner curved line of the occipital bone outward and forward to the temporal. Since the superior longitudinal sinus or sinuses (for it is at times a double channel) generally passes undivided to one side, that lateral sinus—more often the right—is the larger and is apt to groove out a deeper sigmoid sulcus upon the temporal bone. It is regularly joined as it bends down and in upon the back of the pyramid by the

superior petrosal, coming back and out from the cavernous sinus; but there is frequently a petro-squamous sinus of notable size which follows the suture of that name and, often tunneling in the base of the pyramid, enters the lateral about the same point. The inferior petrosal sinus makes little impress upon the temporal bone, as it follows the line of suture with the body of the sphenoid; yet like the other feeders of the lateral sinus it receives countless twigs from the interior of the temporal bone and can easily be the recipient and transporter of much septic matter. Another vessel, the mastoid emissary, is a branch of the sigmoid sinus just as it begins its second curve, and has been described at times as being also a feeder of the lateral sinus. Rarely, although I have myself seen two cases and Zuckerkandl described one long since, the entire lateral sinus turns out through this opening and feeds the external jugular instead of the internal; then and probably always, the blood current must be outward by this rightly named "emissary." Tunneling far at times through the back of the temporal bone, this vessel is decidedly open to injury in operations at this part of the cerebellar fossa, as I have learned to my cost. One other important sinus has a relation to the temporal bone commonly forgotten. This is the cavernous sinus at the tip of the pyramid, which may not only be involved in caries of this extremity of the temporal bone, where pneumatic cells may often be found communicating with the antrum and perhaps sharing in its suppuration, but also receives venous twigs from it which may convey infected blood.

Besides these striking and rather regular extrinsic blood channels, there are numberless small nutrients of the bone, as we may term the veins as well as the arteries; and wholly within its walls there is much diploetic structure abounding in vessels often of considerable size. My studies have not confirmed Zuckerkandl's estimate of the frequent occurrence of much diploe in the mastoid process; pneumatic bones with little if any diploetic structure have been the rule in my series, larger than his; yet none are wholly free from such structure in the squama and elsewhere. The importance of this, wherever met with, has been made clear by surgical pathology in general; but surgeons, general and special, are not so careful as regards it as they should be. The needless opening up to infection of considerable areas of such diploe must aid greatly in the dissemination of septic matter through the system; as must also the timidity which leaves such areas uncleansed after infection. The importance of this is not duly weighed by many in their work or their inaction, unless pathologic investigation has given them occasion to note how fatal intra-cranial or pulmonary disease has spread from such sources. It is in the curious cases with direct continuity of lesion extending inward that they are most interested; yet very little experience should show them case after case in which no demonstrable channel for infection can be traced for the extension of aural infection to the meninges of the brain.

Minute but of importance far beyond anything their size would suggest, are the numerous small vessels which dip into the bone with the offshoots of fibrous tissue from the dura mater, most marked at the petro-squamous suture and the subarcuate fossa. Neither of these prolongations is of much prominence except in early life, and the vessels shrink much with decrease in size; yet at each of these positions septic

infection has been demonstrated and the unproven instances of such invasion are doubtless not infrequent.

THE RELATION EXISTING BETWEEN BRIGHT'S DISEASE AND CERTAIN EAR SYMPTOMS.

Presented to the Section on Laryngology and Otology, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY FRANCIS DOWLING, M.D.
CINCINNATI, OHIO.

During the past year a limited number of cases of ear affections have come under my observation where there were certain well marked symptoms such as tinnitus aurium, dull aching pain referred to the region of the mastoid, more or less reduction of the hearing power, slight irregularity in the gait, etc., where there were no appreciable pathologic conditions of the structures of the ear as far as could be ascertained. In most of the cases the patients were of large fleshy build and over-fed appearance and examination of the urine showed the presence of more or less albumin.

I present two cases for discussion as to whether there was not a possible connection between the ear symptoms and the organic disease of the kidneys.

Case 1.—Benjamin B., aged 50, a plumber, consulted me March 4, 1893, complained of dull aching pain in the region of the mastoid. The pain was not increased by firm pressure over mastoid region and there was no swelling. Ear drums on both sides were intact, and presented slight spots of calcareous degeneration. Hearing power reduced to fourteen inches, by the watch, on the right side and eighteen for the left. Had noises in his ears that troubled him greatly, particularly at night. The patient stated that at the battle of Murfresboro, in 1863, he was struck by a piece of shell. His hat was torn and he was knocked senseless to the ground by the concussion. He had a scalp wound which bled freely, but after it was dressed he was able to resume his place with his company and fought until the battle was over. No particular ill effects were experienced until about three months afterward when he was taken suddenly with dizziness and irregularity in walking, also severe headache. The dizziness and irregularity in walking disappeared in about a week or ten days but the headache continued, coming on periodically. He has had some aching pain in the right side of the head, back of the ear ever since. Tinnitus aurium came on in the fall of 1889, and has bothered him more or less to the present time.

Patient died August 4, 1893, and for a month previous to his death had gradually failing vision and three or four days before death, which was due to Bright's disease, the condition of the vision was reduced to the bare perception of light. The pain in the head and the tinnitus aurium continued almost to the last. The urine was loaded with albumin during the period of his last illness. The physician who attended the patient informs me that the patient died in a comatose condition, presumably from uremic poisoning. No postmortem examination was made.

Case 2.—Mrs. H., a large fleshy woman, aged 48, consulted me Feb. 6, 1897, complaining of dull, aching pains deeply seated in both ears, there was slight unsteadiness in walking, and there was a perceptible reduction in the hearing power of both ears. The ear drums were intact, and presented no pathologic changes except some thickening, bone conduction normal. Tinnitus aurium was very troublesome especially at night. Examination of the urine revealed an appreciable quantity of albumin and some casts.

I could find nothing bearing on this subject in medical literature although I examined a number of the best known works on diseases of the ear. I think, however, that in the cases mentioned, the disease of the kidneys stood in a causative relation to the symptoms which were manifested in the ears. This might take place from the retention of morbid matters in blood, through obstructed drainage on the part of the

kidneys. These retained matters acted by producing a toxic irritation of the filaments of the nerves of hearing as they spread out in the labyrinth, possibly involving at the same time some structural changes in the texture of the nerve filaments. It also seems to me that there might be some structural changes possibly brought about in the nerve filaments through an albuminous exudation with its secondary degenerative changes, similar to those produced in the retina in the condition known as retinitis albuminurica. Among the first effects of such an exudation would be an increase in the pressure exerted by the contents of the labyrinth, which might on its part account for the tinnitus aurium, and also for the irregularity of gait. The degenerative changes following this stage, such as a fatty or a fibrinous degeneration, might be sufficient to account for the reduction in the hearing power owing to the disorganization of the nerve substance in a greater or less degree.

SOME FURTHER RESULTS IN TREATING EARS BY MASSAGE METHODS.

Presented to the Section on Laryngology and Otology, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY LOUIS J. LAUTENBACH, M.D.
PHILADELPHIA, PA.

During the past year I have persevered with my tympanic massage treatment, and the results but confirm those obtained in the past. The results, so far as the relief of deafness is concerned, continue favorable, the tinnitus, unless attended by severe aural vertigo, usually disappearing also. These results are nearly uniform and can be demonstrated readily. It is a method that if properly applied is painless and harmless, and one that seems borne out by common-sense reasoning.

Diseased ear structures occasioning tinnitus and poor hearing are usually of the nature of closed or obstructed Eustachian tubes; diseased and thickened structures within the middle ear, such as ankyloses or hindered articulations, thickened, retracted and adherent membrane, or a nerve which either from disuse or pressure, or both, has become dormant.

My massage machines, which are applied to the auditory meatus, occasion a suction action (or in a few cases a pressure force) upon the membrana tympani, which in turn serves to attenuate the air within the tympanum and to thus open the Eustachian tube, to start the ossicles into motion, increase the circulation of the tympanum and thus cause absorption of the thickened membranes and diseased structures, and, directly acting on the drumhead, it serves to gradually loosen it from the promontory when attached. The method when properly applied, and for a sufficient length of time, repeated as necessary, will usually, at least in some measure, produce the effect required. The pressure upon the nerve is relieved as soon as the stapes begins to resume its normal elastic hold in the window, which is partially accomplished by direct suction action and partially by the increased health conditions occasioned in the structures at the juncture with the fenestra ovalis. In addition the method by sound throwing into the ear rhythmically while the suction effect is continued wakes up a nerve dormant from disuse. This method is practically the same that we see used in surgery every day; a leg on being

removed from its plaster envelope finds its muscular and nervous energy impaired, the masseur is called in to manipulate the muscles, the electric current being used to re-establish the nerve tone.

It is true in the ear we have in addition a diseased condition, the non-use and the disease acting and reacting upon one another to continually increase the pathologic conditions. Restore the mechanical action in an ear and you do much to cure the disease. This restoration of the normal mechanical functions of an ear seems to be one that has not been properly met. Too often ears are considered as being in danger of becoming worse as soon as efforts directed to this end are commenced. I contend that the sooner, in any case of ear disease unaccompanied by severe acute inflammation, efforts directed to the restoration of the normal mechanical functions are made the better, and within reasonable limits, the more persistently and continuously applied the more perfect will be our results. I believe that if this doctrine was invariably acted upon the number of chronic catarrhal ear cases would rapidly grow less. I know of no method which can more efficiently meet this indication than that of tympanic massage, in connection with the old and well tried forms of ear treatment.

I now apply my massage instruments even to all acute cases of tympanic and even of mastoid disease at the earliest possible moment, and use it long and often, adapting its force to the conditions presented, and have been rewarded in often having perfect hearing restored within two or three weeks, whereas, formerly I would usually fail to get as good a result, and if obtained it would be only after prolonged treatment. I consider the method a means of displacing most of the operations on the ossicles, as by its mobilization of the ear structures can usually be produced, and when it fails it will be the differential factor in separating those in which an operation is to be considered.

In this connection I will note three cases:

Case 1.—Miss A. H., aged 21 years, had the chain of bones removed in 1887. There was little or no permanent improvement of hearing, and when I commenced to use phono pneumo-massage she could not hear a clock or watch on contact. By persistent massage she at last heard an ordinary watch immediately upon the ear.

Case 2.—Mrs. E. H., aged 45 years, after la grippe, developed tinnitus and occasional vertigo, and in one ear she could barely hear the watch on contact. She was advised by an ear specialist to have one or more of the ossicles removed, but refused the operation. A year and a half later the conditions being worse, I commenced massage treatment with the result that her hearing is fair, watch being heard about thirty inches. There is no vertigo, and tinnitus only appears upon the advent of a severe cold with its attendant uric acid symptoms.

Case 3.—Mrs. J. B. K., aged 64 years, who has been deaf thirty-five years, and has been treated by several specialists without results, was informed that an operation was her only refuge, but she refused it. Last week, after two applications daily of about three hours each for five days, she heard a clock at over two inches, which before she could not be sure she heard on hard contact.

To illustrate the results obtained in ordinary cases of non-suppurative disease. I report the following cases:

Case 4.—Dr. S. H. S., aged 32, deaf nineteen years, right membrane thickened, retracted and adherent, with little or no ossicular motion demonstrable, hearing distance right ear watch light contact: closed clock five inches; left ear, watch ten inches, closed clock fifty-two inches. After two months treatment twice a week he hears right ear watch three-fourths inch: closed clock seventeen inches; left ear watch twenty-two inches: closed clock seven feet.

Case 5.—Dr. W. D. M., aged 30, deaf ten years, hearing distance, right ear watch one-fourth inch, closed clock six inches; left ear watch not heard on contact, closed clock one and one-

half inch. After three hours' application hearing in right ear watch three inches, closed clock fourteen inches; left ear watch one inch, closed clock nine inches. (Obtained in three months' treatment.)

Case 6.—Mrs. M. F., wife of a physician, was treated by one of our best specialists without results. She has been deaf for six years. When she came to me hearing in right ear, watch eight inches, closed clock three feet; left ear, watch not heard, closed clock not heard. After about fifty treatments she hears, right ear, watch fourteen inches, closed clock seven feet; left ear, watch not heard, clock three inches.

The suppurative cases are among the most responsive to the method. The massage serves to cleanse the middle ear cavity, while otherwise it has the same effect as noticed in the catarrhal cases. This cleansing is more thorough than can be accomplished in any other way, and I find that cases which have been treated for years in other ways, will often cease suppurating and the drumhead heal within a few months.

Case 7.—Mr. A. H., 15 years old, suppuration with right ear no watch hearing: left ear on light contact. We obtained after about fifty treatments a hearing distance for the watch of over fifteen inches in each ear. This case had received an unfavorable prognosis from first-class specialists.

Case 8.—Mrs. R. W. K., aged 38 years, deaf from suppuration caused by scarlet fever during first year of life, had never heard thunder until after the massage treatment was instituted. She improved until she could hear the watch about twenty inches in each ear.

Case 9.—Mr. G. S., aged 14 years, with bare contact hearing in one ear and no watch hearing in the other, developed a hearing of over thirty inches, with cessation of the suppuration and closure of the perforations after about forty treatments.

These three cases have all been without treatment for six months or more, and illustrate an important factor, the permanence of the improvement. It is not evanescent if persisted in: it must be continued until the diseased processes are overcome by the reactive tendencies of a healthy circulation and a restored mechanical action.

Case 10.—Miss A. H., aged 25 years, after being treated for suppuration over a year by a specialist with little or no result, has received a marked increase of hearing by the mixed masseur. Watch was heard right ear hard contact: left ear light contact: is now heard right ear five inches; left ear eight inches.

Case 11.—Miss M. K., aged 13 years, after treatment for suppuration by two specialists, and a mastoid operation by a general surgeon, has been placed on ear massage treatment. As a result there has been considerable increase in hearing and a marked decrease of the suppuration. The hearing was, right ear watch one-fourth inch, closed clock five inches; left ear light contact, closed clock four inches. She now hears, right ear watch six inches, closed clock eighteen inches; left ear light contact, closed clock six inches.

Case 12.—Miss E. S., aged 18, who has been examined by two or three specialists, all of whom gave an unfavorable opinion as to the restoration of hearing, has after twenty-five visits improved from a hearing distance in right ear of watch three-fourths inch, closed clock six inches to two inches and eleven inches respectively, and in left ear from watch one-fourth inch, closed clock two inches to one and one-half to eleven inches respectively.

I claim for the method when applied in a thorough and rational manner, that it will in part or wholly restore the normal mechanical action of the conducting apparatus, and will help to open the Eustachian tube more completely and induce a more healthy action in the middle ear, while it will stimulate the auditory nerve and often relieve it from the pressure which, when sufficiently long continued, would destroy its functions. Its indication after an acute middle ear or mastoid disease is evident, and thus used it would prevent the development of the multitudes of chronic catarrhal, sclerosed and chronic suppurative ears now so prevalent. In cases of suppuration its cleansing action in addition to its other reparative effects makes it a most valuable agent, and cases other-

wise irremediable succumb to its action. It is valuable in differentiating cases of ear disease in which an operation is required; when the method fails in improving the hearing and relieving the tinnitus, then the necessity of an operation on the conducting apparatus is to be considered, and not until then does this question arise.

Patients with ear disease are often deterred from seeking advice because of influences which have been at work from time immemorial to make them think that work on the ear means a decrease rather than an increase of the hearing function. It will take time to overcome these wrong tendencies. Even in our public schools the text-books are very prone to make mistakes. Within a week I have found in a text-book called "*Our Bodies and How We Live*," by Dr. Blaisdell, the following statement as to the drum-head: "If once broken this delicate membrane can not be repaired and deafness results." This book is used in a large number of American cities. Such books have a most pernicious effect, and these impressions should as far as possible be corrected.

1723 Walnut Street.

DISCUSSION.

Dr. ELLEGOOD—I ask whether Dr. Lautenbach observes more benefit from the sound or the motion, or from the impression made on the mind of the patient. I have used phono-massage and found it without benefit. The instrument which I used was called the violin vibrophone. It was easily put out of order. Tinnitus was only improved in a few cases. I do not think that any treatment of tinnitus is always satisfactory from the fact that the causes are so very variable.

Dr. BURNETT—As Dr. Lautenbach has laid much stress on the work done by the conductors, I should like to know how the result was brought about when there were no conductors to work. I should like to know whether adhesions will not recur, as in every other method?

Dr. RANDALL—I believe the instruments based on phono-massage are all mistakes. They have all proved, under trial, to be capable of mischief. It is known that the vibration of tuning forks will cause cataract in the eyes of animals, and if long continued will destroy the function of the nerves of sight. Most of these instruments just fail of being a complete success. On the other hand they often do harm.

Dr. KYLE—I ask if Dr. Lautenbach has tested the hearing of the patients at different times without treatment, to see whether the same variations of hearing did not occur? In a number of my cases the same variation has occurred without treatment.

The CHAIRMAN—The statement regarding the drumhead found in a public school text-books is perhaps responsible for some of the difficulties under which the physician labors when he wishes to puncture the drumhead as a remedial measure. Otherwise well informed people have the impression that an intact drumhead is essential to hearing, and that total deafness will result if there is any aperture there.

Some years ago when the phonograph method first became popular, some of my patients insisted on having this treatment, and though I could not understand, theoretically, how it could be beneficial, I tested the method for a period of several months, and was discouraged before the patients were. I can report no good results whatever. Since that time the phonograph has disappeared from my office, and this elaborate apparatus has now made its appearance. I have not had the courage to hold out hopes to these patients, knowing that in so large a percentage of cases no permanent improvement was perceived. I think that much benefit can be secured by pneumo massage.

Dr. LAUTENBACH—The question has been asked whether there is more benefit from sound or motion. These are all pneumo-massage machines, and with that you can use phono-massage if you wish. I have not found phono-massage of peculiar value, but pneumo-massage is very valuable. The combination of the two in my hands has proved most excellent. I do not use phono massage alone at all. I think it is directly applicable to a nerve which has become dormant. It simply stirs up the nerve fibers to renewed activity. The machine not only restores mechanical functions, but is intended to put the middle ear cavity into a condition as nearly normal as possible by stimulating the circulatory apparatus. As to Dr. Burnett's

remark about the removal of the conductors, there was formed in the middle ear cavity a membrane closing over the middle ear. The facts are simply that the ossicles were removed and hearing did not improve. The patient could not hear at all. After my treatment a watch could be heard on contact.

As to adhesions recurring, under ordinary operative conditions they would have to recur, but under this method they would not necessarily recur. As to mastoid disease, I do not wish to say that this method has any effect on mastoid disease. What it can do is to prevent mastoid disease from diminishing the hearing as much as it otherwise would.

THE IMPLANTATION OF STERILIZED ROOTS OF ANIMALS' TEETH CARRYING ARTIFICIAL CROWNS.

Presented to the Section on Dental and Oral Surgery, at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June, 1-4, 1897.

BY WM. ERNEST WALKER, D.D.S.

PROFESSOR PROSTHETIC DENTISTRY, DENTAL DEPARTMENT SOUTHERN MEDICAL COLLEGE.
ATLANTA, GA.

It is a deplorable fact that notwithstanding the great advances made in the treatment of the various diseases of the oral cavity, occasionally a tooth is lost in spite of all the best endeavors of the stomatologist to prevent such a calamity. It is therefore very desirable that we should be able to replace such lost organs, and often by other means than plate or bridge-work. I need therefore make no apology for bringing before you the subject of planting teeth.

Since the introduction of the operation of implantation, by Dr. Wm. J. Younger (1885) various substitutes for carrying artificial crowns—as lead capsules, porcelain teeth, double staples of metal reversed, etc., have been tried. The literature on the subject does not indicate any marked degree of success with any of the roots save natural ones.

As it is often a difficult matter to obtain a healthy root of a human tooth suitable for this purpose, it has occurred to me that we might utilize the roots of the teeth of animals, which are easily obtained from the slaughter-pen and which are as a rule free from disease, requiring however thorough sterilization. Before implanting they can be surmounted with Logan or other crowns, a cast made of the mouth and a bandage made on it by Dr. Jacks' method, which I have found the most satisfactory.

While I have not found any animal teeth with roots very closely corresponding to those of human molars, this is immaterial as the socket from which a molar has been extracted, requires remodeling even to receive a human molar, for the roots of no two human molars are alike, and less cutting is necessary in using the large single root of a bovine central incisor, all that is demanded being the removal of the septum dividing the alveoli of the socket. I have examined a number of heads and find that while bovine centrals are very well developed and admirably adapted to this purpose, it is not so with the lateral incisors at the age of which beef is usually slaughtered in this section of the country, the root of the lateral not being fully developed and the foramen very large.

This is not, strictly speaking, implantation, but a practical transplantation, which might be practiced by some who are hesitating to drill sockets in the molar region for implantation, or who might be deterred by the difficulty of inserting a multi-rooted tooth.

I will not lengthen this paper by going into the details of the removal of pulp, sterilization, canal filling, adjusting artificial crown, etc., for any necessary

variation in the procedure from what has been published on im- and trans-plantation will naturally suggest itself to any one who will take the trouble to review the literature on the subject before undertaking the operation.

TUMORS OF THE MAXILLA.

Presented in the Section on Stomatology, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY WILLIAM KNIGHT, M.D., D.D.S.
PROFESSOR OF ANATOMY AND ORAL SURGERY, OHIO
COLLEGE OF DENTAL SURGERY,
CINCINNATI, OHIO.

In this paper it is intended to describe briefly some of the more ordinary neoplasms of the maxilla.

The upper, as well as the lower maxillary bones, besides being subject to diseases affecting other bony structures of the body, are liable to the invasion of neoplasms peculiar and limited to themselves; among these may be mentioned the epulides, dentigerous and multilocular cystic tumors. The pathologic congeners of the epulides may, however, be found in other parts of the body, but it is not customary to call every growth found arising from the gums or from the periosteum of the alveoli an epulis.

Two, and only two, distinct forms of epulis are to be recognized as affecting these bones. The recognition of these is of importance, not only from a pathologic, but mainly from a surgical standpoint, as deciding the proper treatment, which is different in the two affections.

The hard or fibrous form is by far the most innocent in its pathologic effects; it is almost identical with the fibrous growths found in other parts of the body, yet it differs from them, mainly in its tendency to form spicula of bone.

The myeloid or softer form is composed of but a small amount of fibrous tissue, the remainder of the neoplasm being largely composed of polynucleated myeloid cells; the first variety is closely connected with the gum, also with the periosteum of the alveolus; it springs from the inner or outer surface, and unless long standing and of large growth seldom, if ever, invades the entire thickness of the alveolar process. The second form, or myeloid variety, is more closely allied to the endosteal than to the periosteal structures and is connected within the alveolus. It has a marked tendency to invade the entire thickness of the alveolar process, and does not attack the deeper portion of the bone unless improperly treated with irritants, when it may assume a malignant condition and quickly infiltrate the surrounding tissues.

The etiology of either form of epulis is somewhat obscure. Both varieties have been observed before the eruption of the teeth of infants. It is, however, generally agreed that some prolonged dental irritation is the usual exciting cause of this affection, as instanced in the following case:

A lady, aged 45, was referred to me two years ago for treatment. She had worn for five years a lower dental plate that had caused her some annoyance, yet was unattended by any special pain.

June 10, 1895, when I examined her mouth, there was seen a small growth the size of a hazel-nut, occupying the bicuspid region of the left lower jaw. She stated that the growth had been present for more than a year, but to her great alarm had enlarged considerably during the past few months. Having consented to an operation, the alveolar process, from the lower lateral incisor to the first molar down to and including a portion of the basilar part of the bone, was removed, when a frag-

ment of the root of the second bicuspid was found imbedded in the bone; this fragment of a tooth had been, in all probability, the original cause of the formation of the tumor, which upon section proved to be a myeloid growth; although the jaw was accidentally fractured toward the completion of the operation, no untoward symptom followed. At the present date, May 31, 1897, the patient is wearing a new lower plate. There is no evidence of any return of the disease.

In all instances in which the surgeon suspects a myeloid epulis, he should not rest content without removing the entire thickness of the alveolar process. There is perhaps no more pitiful story for a surgeon, when a case of this kind returns to him with a sarcoma occupying the seat of the former operation, with perhaps infiltration of the floor of the mouth, than to declare that permanent relief is almost hopeless, and to believe that if more of the jaw had been removed during the operation, this might not have happened. This was forcibly recalled to the writer's mind in a recent case at the clinic of the Ohio Dental College.

The patient, a woman aged 32 years, had been operated on by another surgeon nine months previous to applying at the clinic. At that operation a small growth had been removed from the left upper bicuspid region. On examination, two growths were seen, one occupying the seat of the former operation, the other located in the right upper bicuspid region; both growths were myeloid in character. It is by no means common to find this primary plurality of myeloid growths, and there is a suspicion that, in this case, the disease is something more than a local one.

Both growths were removed, and although it is early to prognose, the patient at the present time is better in spirits and health than she was, and there are no local manifestations of a return of the affection.

In the treatment of myeloid epulis, in consequence of the extensive involvement of the alveolar portion of the bone, even as in this case, when the growth apparently springs from one plate only, radical measures must be insisted on. It is always the wisest plan to remove the entire thickness of the process, sacrificing whichever tooth may be deemed necessary to effect a thorough removal of the disease. It is in these cases that imperfect operations are more than useless, for when imperfectly removed, it is the unfortunate tendency of myeloid epulis to return in a still more malignant form. This fact is so well recognized that no operator, in treating these cases, should be satisfied unless he removes outlying tissue beyond the apparent extent of the growth. The best method to be employed for the purpose, is to saw completely through the alveolar process on each side of the disease and then, with one of the various forms of cross-cutting bone-forceps, remove the entire piece of bone with the tumor. It is my invariable practice, after having removed the affected piece, to use the bone-gouge freely, so as to remove every vestige of the disease. The free hemorrhage which arises in these cases is easily controlled by pressing a few small pledgets of cotton into the wound; the hemorrhage having ceased, compresses of cotton, saturated with a weak boracic acid or a permanganate of potash solution, can be gently pressed into the wound; these compresses are readily retained in position without much inconvenience to the patient, by his simply keeping his mouth closed. External bandaging is seldom required. Twenty-four hours having elapsed since the operation, the compresses may be removed, and the mouth should be rinsed four times a day with a solution of 0.32 grains of permanganate of potash to 30 c.c. of water. In ordinary cases no other treatment is required.

In the fibrous or hard form of epulis, it is seldom

necessary to remove the entire thickness of the alveolar process, although it is advisable always to remove either the inner or outer plate upon which the growth is attached: it is prudent, in order to effect a limited destruction of the bone, to touch the site of the removed growth with the actual cautery; those who object to the use of the cautery can produce the same result by touching the part with nitric acid, chlorid of zinc or the trichlor-acetic acid. It is seldom necessary to sacrifice the teeth contiguous to the tumor, as the unremoved plate is sufficient to retain them in place, and in many instances, years after the operation, the teeth are found to be firm and in good condition.

Cystic diseases of the maxillary bones are perhaps more frequently due either to disease of fully developed teeth, or they are associated with teeth that have been imperfectly developed. Cysts from either one of these two causes may attain a very large size, giving rise to absorption, to a greater or less extent, of the walls of the maxilla without in so doing giving rise to much inconvenience to the patient.

It is claimed by Broca, whose views on this subject meet with general recognition, that the majority of cysts of the jaws have their origin in tooth follicles. It is held that the soft gelatinous enamel organ, being easily affected by morbid influences, readily disappears, leaving in the follicle a cavity which is ready to be transformed into a cyst. Some of these cases seem to arise without any appreciable cause; an instance of this kind was referred to me four years ago by Dr. F. Sage of Cincinnati.

The lady, 46 years of age, had, occupying the right side of the lower jaw, a small cystic tumor in the bicuspid region: the tumor had been of slow but continuous growth; at no time during the development had pain been experienced; she sought medical counsel partly on account of the inconvenience of its increasing size, but mainly from the fear that so often possesses the laity, that whenever a growth appears on any part of the body, it must of necessity be a cancer. Careful inquiry into her history failed to elicit any fact that would give a clue upon which an opinion might be founded. Both dentitions had been normal and the teeth in the immediate neighborhood of the growth were in good condition. A careful search was made during the operation to discover any probable cause that might have produced a tumor, but none was found. Four years have passed since the operation, and there has been no return of the affection.

Although the etiology of cystic tumors occurring in the jaw bones, has in recent years been elucidated to a very large extent, much still remains in doubt. Mr. Christopher Heath, in his work on the "Diseases of the Jaws," has made particular mention of the views held by Mr. F. Eve,¹ as to the development of multilocular cystic tumors of the maxilla. Mr. Eve maintains that so far from multilocular cystic tumors having a dental origin, they are on the contrary produced by an ingrowth of the epithelium of the gum. This class of tumors frequently follow injury, or irritation of decayed teeth, or long continued inflammation which has lead to an increased supply of blood to the parts; they are slow of growth, do not affect the lymphatic glands, nor infiltrate the surrounding parts. These tumors are innocent in character, but owing at times to their enormous increase and multiplicity, they not infrequently necessitate the removal of the larger portion of the lower jaw, which bone is specially affected by the disease.

The treatment of cystic tumors necessarily varies according to the form of the cyst; if it be a single cyst connected with a fang of a tooth, the extracting

of the offending body will usually be sufficient to effect a cure; if, however, it be of larger size and has caused some expansion of the bone, an incision through its bony wall will be necessary; this operation will evacuate the fluid, which is usually of a dark clear color, unless inflammation has been present, in which event, the contents will be of a more purulent character. It is also the best practice to cut away a good portion of the cyst wall, as otherwise the cyst is liable to rapidly reform. In all instances in which a tooth is suspected of being present within a cyst, a careful search for it should be made, for it is obvious that resolution will be impossible so long as the tooth is retained. In both of the above instances the after treatment consists in simply using, four times a day, an antiseptic and slightly astringent mouth wash. In cases where a portion of the wall of the cyst has been removed, the cavity should be plugged with boracic acid gauze or lint that has been saturated with a solution of permanganate of potash. This packing might be removed and a fresh one used if necessary in forty-eight hours time.

But in the treatment of multilocular cystic tumors more radical measures must be adopted. If any suspicion exists as to the possibility of a sarcomatous complication, which is not infrequently the case in this character of growth, the removal of the portion of the affected bone is always recommended, and has been the usual procedure; if however, the diagnosis can be satisfactorily determined as to the absence of a malignant factor, the operation as recommended by Mr. Butcher of Dublin, can be performed. This operation consists in dividing the mucous membrane covering the cyst, and then with gouge and bone forceps or chisel and mallet, thoroughly removing all of the affected parts. The success of this operation depends entirely on the completeness with which this is done. Mr. Butcher has had very marked success with the cases of multilocular cysts that he has treated by his method; other operators, however, have had only partial success by following the plan advocated by Butcher; their comparative failure may perhaps be attributed to their having left a portion of this diseased structure unremoved.

A malignant tumor composed of the same structural elements differs in its clinical history according as it attacks the soft or the bony tissues, and differs also in bone, as to whether the compact or cancellous tissue is involved. Thus a round-celled sarcoma will not infrequently develop within the interior of the lower jaw, and will give rise to no other symptom, than perhaps enlargement of the bone. This condition may continue to exist for several years before the tumor has attained the size of a walnut, the patient during all this period complaining only of the small deformity caused by the slowly growing enlargement. What a contrast this offers to the rapidly growing sarcoma, as it occurs in the softer tissues! This difference of growth in the same structurally formed neoplasm, may partly be explained by its elementary formation. All varieties of the sarcoma belong to the type of the embryonic connective tissue: the cells of which they are mainly composed have no definite arrangement; they are in constant relation with the stroma, and consequently the cell not being surrounded by alveoli, as in the case with the carcinomata, have a marked tendency to infiltrate the neighboring tissues at a very early period. The blood vessels of a sarcoma ramify among the cells, and are very thin walled,

¹ Eve: British Medical Journal, Jan. 6, 1883.

hence, the frequent occurrence of hemorrhage into their substance, and their rapid dissemination through the vascular, and not the lymphatic system of vessels.

The compact tissue of bone antagonizes to a marked degree the favorable conditions for sarcomatous growth; this is especially the case when a sarcoma develops between two plates of bone, as when a neoplasm of this character forms in the interior of the lower jaw. Occupying an intermediary position, clinically speaking, between the rapidly growing sarcoma of the soft parts, and those slow growing ones occurring in the lower jaw, are those instances of sarcoma originating in the connective tissue of the mucous membrane lining the antrum of Highmore; this is by no means an uncommon location for the development of primary sarcoma. The history of all such cases is very similar. The sufferer complains of pain which is often referred to a tooth in the affected jaw. The offending member is sometimes treated, more frequently, however, is extracted, while the relief, if any, is but temporary; the uneasiness and pain continue, with perhaps some intermission. This condition may, and usually does, continue for a considerable time before any swelling of the part is observed; after the swelling appears the disease is apt to increase rapidly, and the growth, which by this time has completely filled the antrum, and has infiltrated the bony walls of the cavity, has a tendency to fungate and bleed readily. A case of this kind was referred to me by Dr. F. Saul.

A man 42 years of age who, for two years past, had had intermittent pain in the upper second bicuspid. Although the tooth was in a sound condition, he had it extracted, without obtaining any relief. Two months previously to coming to me, a slight swelling appeared on the right cheek, and a suspicious looking growth in the alveolus of the extracted tooth. He had some pain almost all the time, which now and then was severe, and was advised to have the right maxillary removed, but dissented. Five months later he returned, the swelling now extending upward under the zygoma, and reaching the temporal region. To operate with hope of permanent relief under such conditions, was extremely questionable, but he was very eager to have the operation performed. The right half of the maxillary bone was removed together with considerable of the surrounding tissue. The tumor proved to be a round-celled sarcoma; seven months afterward the disease returned and a second operation was performed. This, for a few months, gave him relief, after which time hemorrhage ensued, and occurring periodically terminated in death.

To a certain extent this case illustrates the clinical history of sarcoma, when originating in the antrum. Intermittency of growth at first, is somewhat characteristic of sarcoma wherever it occurs. This was followed by a slow but continuous enlargement, and, finally, after the bony walls of the antrum had yielded by a rapid increase in growth with infiltration of all the surrounding parts. The treatment of sarcoma must be radical, and any contemplated operation should be done as early as a diagnosis can be made. As long as a sarcoma is confined within the bony walls of the antrum, a hopeful result as to a permanent cure can be looked for, but after this disease has passed beyond these confines, any operation, however heroic it may be, will usually result in failure, as it is almost impossible to remove all of the affected tissues. I always refuse to operate in advanced cases of sarcoma of the upper jaw, without informing the patient, or his friends, of a probability of the return of the disease, and agreeing to operate simply as a means of temporarily relieving the suffering of the person so affected.

Let us defeat the Antivivisection Bill!

SOCIETY PROCEEDINGS.

College of Physicians of Philadelphia—Section on Otology and Laryngology.

Stated meeting March 1, Dr. E. L. Vansant in the chair.

Dr. F. WOODBURY read a communication on

NEUROTIC OR PARADOXIC COUGH,

and presented a case to the members for examination. It was that of a woman 48 years of age, who, when first seen last December, suffered with a peculiar spasmodic cough, consisting of a single explosive effort, recurring with considerable regularity once or twice every minute. There was no expectoration and no pain, but with each cough the head was turned violently to the right side and the face was contorted. The patient was subject also to headaches and constipation. She gave a history of having had a severe nervous shock about ten weeks previously, owing to the death of a son with consumption; she had lost much sleep while nursing him for months before his death. Upon examination the larynx and lungs were found to be healthy. In the nasopharynx the mucous membrane was hyperemic in the vault. The nasal chambers were also hyperemic. The inferior turbinates were swollen. These were shrunk by an application of 10 per cent. solution of cocaine, and a sharp spur was seen projecting from the septum and pressing against the left middle turbinal. When this spur was touched with a probe the patient experienced a tickling in the larynx and an irresistible impulse to cough. As the nose appeared to be the site of reflex irritation causing the cough, it was stated that the removal of the spur and the reduction in size of the turbinates by the galvanocautery would probably give entire relief. Under systemic treatment with bromids to reduce the nervous irritability, and laxatives to overcome the constipation, she had already been greatly benefited and had recently gone as long as five days without a cough or headache. Two other cases were reported, one in which the site of reflex irritation was in the throat in a mass of glandular tissue below the left tonsil; in the other one a case of ear cough. A case of persistent cough due to glandular hypertrophy at the base of the tongue was also referred to, which had been shown by Dr. Donellan at the last meeting of the Section. These cases were described as instances of neurotic or paradoxic cough, inasmuch as the site of irritation was not in the throat or chest, and treatment of the cough was unavailing, except to direct attention to some abnormality which required diligent examination into various sources of reflex irritation. Without such careful search a case might be dismissed as one of hysteric or gouty, or so-called "stomach cough." The necessity of both local and general treatment was pointed out by the reporter. In conclusion, he warned against mistaking a cough, caused by tuberculous infection of the lungs, and previous to the development of sufficient pathologic changes to afford characteristic physical signs in the chest, for merely a nervous laryngeal cough; here the altered temperature, the pallor of the larynx and possibly the detection of the bacilli in the sputum, would suggest the true nature of the case and its proper treatment. Such a case might be neurotic, but would not be a case of neurotic cough in the sense in which it is used in this communication.

Dr. P. S. DONELLAN mentioned a case of obstinate cough, which, after death, was found to be due to aneurysm of the arch of the aorta. Irritation of the recurrent laryngeal nerve was suggested as the cause of the cough. He inquired with regard to the so-called stomach cough, if it occurred at all, and if so, with as much frequency as the popular references to it would seem to imply.

Dr. WOODBURY said that an overloaded stomach was a frequent cause of croup in young children, and indigestible food will often excite asthma in susceptible subjects; therefore the possibility of a stomach cough as a symptom of indigestion might be admitted, but it must be extremely rare, in proportion to the great number of cases of dyspepsia in which no cough is present. To warrant such a diagnosis, there should be entire exclusion of other sources of reflex irritation, the symptom should only be present after eating food and during the act of digestion and susceptible of entire relief by careful selection of the diet. It is very probable that many cases of so called stomach cough are really instances of reflex cough from glandular hypertrophies at the base of the tongue, or some other form of neurotic cough similar to those mentioned in the paper.

Dr. VANSANT said that it is a very frequent occurrence, in examining the nasal chambers, to have a patient cough in your face which is a very disagreeable experience when the patient has an infected cough or bad breath. As a protection, he had

found it useful to direct the patient to hold a handkerchief in the hand ready to bring it up before the mouth when he coughs.

Dr. E. L. VANSANT presented a

CASE OF ACUTE EMPYEMA OF THE FRONTAL SINUSES.

A little girl, 11 years of age, was shown, who three weeks ago had an attack of cold, which probably was the grippé. She had a cough and a discharge from the nose since that time. The mother was anxious about her because a sister, 16 years of age, had died a few weeks ago with consumption. The child now has purulent rhinitis with acute empyema of the nasal chambers. The question of treatment was suggested for discussion. The reporter's own experience had been that when such cases are given early treatment, they make a good and rapid recovery. After only twenty-four hours treatment the present case had very much improved; her cough had lessened; the tenderness over the frontal sinuses had almost disappeared and the secretion was materially reduced. The treatment consisted of active purgation, followed by frequent use of warm alkaline wash, and hot moist applications to the frontal sinuses, externally, with clearing away of secretions from the mouths of the sinuses. The patient was also kept indoors. The relief here has been a quick one; rather quicker than usual in his experience of such cases.

Dr. GIBB—Empyema of the accessory sinuses is quite a frequent supplement to influenzal attacks. They generally recover with careful management, but I have not seen any get well so quickly as this one. Last summer, a young man who, while traveling in Yellowstone National Park, inhaled the alkaline dust, and had in consequence acute inflammation of the nasal chambers extending into the accessory sinuses, but confined to one side. After cleaning the outlets, thus securing proper drainage for the frontal sinus, and the usual local and general hygienic measures, the patient got well in the course of a week.

Dr. EMMA MUSSON, a guest, asked about the effects of the direct application of oxygen in these cases. In several cases coming under her own observation good results were noted. A prominent specialist had advised opening of the maxillary sinus in one of these cases, which yielded very promptly in the course of a few days, to oxygen applied three times a day. After reading Stokes' paper on the treatment of acute otitis media by this method, she had tried it in sinus disease. Subsequently she had read that it had also been applied to the treatment of purulent discharges from the nasal chambers and accessory sinuses.

Dr. DONELLAN said chronic cases give the most trouble. He reported the case of a woman who had suffered with headache for two years, and he had discovered empyema of the right frontal sinus, with hypertrophied turbinates, the headache being caused and aggravated by the damming up of the outlets. Last week he had seen Dr. Delavan remove the anterior end of the middle turbinated bone with the punch forceps, and he subsequently washed out the sinus with a 50 per cent. alcohol. The case has been very much improved since the treatment.

Dr. J. S. GIBB presented a case of

NEW GROWTH IN THE LARYNX

for examination. It had a papillomatous appearance, resembling what has been described as pachydermia laryngis. The patient had been before the Section some months ago and he had brought him back by request in order that the Fellows might watch the case. The growth appeared to be about the same size as when previously shown. He had removed a piece for examination, but the place had been soon filled up again. The growth is on the right side of larynx and extends from the arytenoid down to and including the true cord. Its broad flat surface has a rough appearance and it is almost purely white. Under the impression that it might be of specific nature, he had been put upon potassium iodid, and while his general condition improved the treatment had very little effect on the growth. From the specimen submitted one pathologist reports that the growth is papillomatous and is an illustration of pachydermia laryngis. A larger piece was submitted to another pathologist, who reports that it is a papillomatous neoplasm with a suspicion of malignancy; for reasons assigned it would be best designated as an adenopapilloma.

Dr. VANSANT said that the case represented an extremely rare condition and was the first one that he had seen. The condition of the tongue termed leucoplakia is frequently seen and it is our experience that such cases frequently become carcinomatous. In a patient, a man who had a rapidly growing epithelioma of the tongue requiring extirpation, he had known that leucoplakia had existed for twelve years. Such a result might be looked for in the present instance, but how

long a time before this would occur it would be impossible to predict.

Dr. WOODBURY asked the reporter if he contemplated extirpation of the larynx?

Dr. GIBBS said: Extirpation of the larynx is a very serious operation and certainly, in this case, one not to be considered at the present time. The report from the pathologists had been obtained with reference to deciding this question, but he did not think that either report would warrant the operation. There is no rapid extension of the growth, no glandular involvement, no deterioration of the general health and nothing to warrant the idea of malignancy at present. The patient will be kept under observation and its course reported to the Section from time to time.

Dr. GIBBS presented a specimen of

MUCOUS POLYP SPRINGING FROM THE NASAL SEPTUM.

This is a very rare occurrence. In a large number of autopsies in which Zuckerkandl had examined the nasal chamber, thirty cases occurred in which mucous polyps had sprung from the middle turbinate bodies and only three presented polyp growths from the septum. The case was that of a woman, 50 years of age, who for several years had had attacks of epistaxis, and more recently had increasing difficulty of breathing through the right naris. About two weeks previous to application for treatment, she had noticed the growth at the entrance to the nostril. Upon examination a polyp was found, which was pedunculated, and it was traced to its attachment on the septum. It was snared off and there was very little bleeding. The spot was touched with the galvanocautery and healed readily. This growth is quite different from the cases recently reported by Pierce of Chicago, of bleeding polyp of the nose, which are instances of fungous fibroma or polypus teleangiectoides. The ordinary causes of mucous polyp were absent in the case just reported, as there was no necrosed bone and no inflammation. If this case proves that it is possible for a polyp to develop at any point in the nasal chambers, without any previous disease or inflammation, it will certainly upset some of our pathologic ideas as to the causes of these growths.

Dr. MUSSON referred to a case occurring a number of years ago, in which she had removed with a Jarvis enare a growth as large as a hickory nut, which had grown from the septum. There was no recurrence of the growth, which was characteristic of growths from the septum.

Dr. P. S. DONELLAN exhibited a

PHANTOM LARYNX FOR THE STUDY AND PRACTICE OF LARYNGEAL DISEASES AND OPERATIONS.

The chief point of interest attached to this instrument was that it was formerly the property of Morell Mackenzie and had been used by him for daily practice. He would drop in small pieces of paper or beads and remove them with the forceps, thus acquiring his wonderful manual dexterity. The advantage of this method of studying the diseases of the larynx over the ordinary flat diagrams or plates in books is very obvious, but its chief usefulness is in the practice it affords in the use of instruments in the larynx, both for diagnoses and operations.

Maryland Public Health Association.

Meeting held at Baltimore, Md., Nov. 18 and 19, 1897.

(Concluded from page 670.)

Dr. CH. WARDELL STILES, Zoologist of the U. S. Bureau of Animal Industry, Washington, D. C., read a paper on

SOME OF THE DANGERS ARISING FROM SLAUGHTER-HOUSES, WITH SUGGESTIONS FOR MEETING THEM.

Generally speaking, he thought the places for slaughtering animals for food might be divided into large abattoirs and local slaughter-houses. The former are usually located in cities and operated in connection with packing-houses. The latter are used chiefly by the meat dealers of the country towns, and the animals slaughtered at such places are generally, if not always, for local consumption. He left the abattoirs out of consideration, making criticisms on the local slaughter-house in its relation to disease. He said some local dealers obtain all their meats from the packing-houses where inspection exists; others drive from farms to farm buying animals and slaughtering them on the premises; still others buy slaughtered animals which farmers bring to town; while the majority of dealers in small towns own or rent slaughter-houses where they do their own killing. In many cases these houses are located on the banks of rivers or creeks into which they drain. Frequently the offal is thrown down the embankment and left there to be eaten by hogs, dogs and rats, or in some parts of the West by Indians, or to decay and drain into the stream. Quite often the slaughter-houses are located on farms, the butcher giving the

offal to the farmer as feed for his hogs, in lieu of paying rent. In case a town is provided with more than one slaughter-house, these houses are generally scattered north, south, east and west, each butcher apparently trying to so locate his house as to prevent any undue amount of curiosity on the part of his competitors regarding the character of his stock. Again, slaughter-houses are usually situated just beyond the borders of the town which they supply. Thus they do not come under the supervision of the local Board of Health; and as few, if any, of the State Boards pay any attention to them, they are without any sanitary supervision. Notes taken on the premises of various slaughter-houses were read illustrating the actual existing conditions. Some places were found in good condition: some in a condition that was a disgrace both to their proprietors and the communities that tolerated their existence. Every slaughter-house is from the very nature of things a center of disease; and naturally the poorer the condition of the premises the more dangerous they are. Even if only a few animals are slaughtered each week, the total number may amount to several hundred during the year. Some of the animals are surely diseased. At least one of the hogs has trichinosis, and when the offal of this hog is fed to other hogs which are raised on the grounds, these hogs can not escape infection with trichinae. But that is not all. Slaughter-houses are often over run with rats: the rats feed on offal, and when feeding on the offal of a trichinose hog, they likewise can not escape infection with trichinae. About 55 per cent. of the rats I have examined from slaughter-houses have been found to be infected with this disease, so that if a hog at a slaughter-house eats a rat the chances are fifty five in a hundred that he will catch trichinosis. Now, suppose that a slaughter-house is burned or abandoned; the rats inhabiting the premises naturally wander to the neighboring farms in order to obtain food, and of every hundred rats which leave the slaughter-house, fifty-five carry with them the disease known as trichinosis. This disease they transmit to hogs if eaten by them. From this it will be seen that every slaughter-house where hogs are killed, is a center for the spread of trichinosis to neighboring farms, and thus forms one of the great factors in keeping this disease alive, so that today about 1 per cent. of our American hogs are infected with trichinae. Yet, fortunately, because of our custom of cooking pork thoroughly, the disease is usually killed before we consume the pork, and our cases of trichinosis in man are thus reduced to the few, chiefly Germans, who eat raw or rare pork.

But trichinosis is by no means the only disease transmissible to man which centers at the slaughter-house. Of the cattle killed during the year, some of them surely have tuberculosis; in many cases, as I said, the entrails of the slaughtered animals are thrown to the hogs on the premises. There can be but one result, and that is to spread tuberculosis to the hogs. Fortunately, we find only about three thousandths of 1 per cent. of the American hogs have to be condemned because of tuberculosis; and here again our custom of thoroughly cooking our pork protects most of us to a great extent against infection from this source.

Another disease, apparently on the increase in this country, and against which we have at the present moment absolutely no protection, is hydatid disease, caused by an animal parasite which passes its adult stage in the intestine of Old Dog Tray, in the form of very small tapeworms, almost the smallest tapeworm known; its larval stage is the largest larval tapeworm known, varying from the size of a bean to that of a child's head, and living in the liver and lungs of cattle, sheep, swine and a large number of other animals, including man. Its complete life cycle is as follows: Starting with the adult tapeworm in the small intestine of dogs, the eggs are scattered on the ground and swallowed by cattle or other animals with the fodder or water. Upon arriving in the stomach the eggshells are destroyed and a six-hooked embryo, which is thus freed, bores its way through the intestinal wall and wanders to the various organs of the body; coming to rest in a suitable place it increases in size, forming a bladder which generates numerous heads, each one capable of developing into an adult tapeworm when swallowed by a dog.

Now, anyone who has had the misfortune to visit a slaughter-house, knows that dogs soon find that these premises are excellent places to obtain food. The butcher of course can not utilize the parasite in his trade, so he throws the infected organ aside, or at least discards the infected portion of the organ. This discarded portion forms a delicacy for the stray or pet dog which happens to be near; and thus becoming infected with tapeworms the dog proceeds to unconsciously transmit this disease to the persons who pet him or to the flocks and herds he is supposed to keep from danger. It is claimed that in some districts of Iceland every sheep of three years old was infected, while it is an exception to find a cow ten years old free

from the disease. In India, about 70 per cent. of the cattle are infected. In Germany the statistics vary for different animals and for different parts of the country, from 1 to 37 per cent. Turning to our own country, we have as yet no exact statistics upon this disease, but at a rough guess, judging from what I have seen at slaughter-houses and abattoirs, I should estimate that about one-fourth to one-half of 1 per cent. of our American hogs harbor this parasite. This worm is the most fatal animal parasite found in man, 50 per cent. of the cases of infection dying within five years. The disease is especially common in man in Iceland, it being estimated that about 2 per cent. of the inhabitants are infected; it is also quite common in Australia where 3000 cases were reported from 1861 to 1882, or about 150 cases per year. In Central Europe the hydatid is found on an average once in every 130 postmortems, while in Rostock it is found in nearly 2.5 per cent. of the postmortems. In our own country the disease is not so common, but one of my assistants, Dr. Sommer, recently compiled for the United States 100 cases which were reported in various medical journals. Taking the world at large, certainly 500 human lives per year would be a very moderate estimate of the victims of this disease transmitted to us by Old Dog Tray.

There has been a regular decrease in Berlin, Prussia, in the number of lungs and livers of cattle and sheep condemned for this disease, the statistics falling for cattle from 4.6 per cent. of the lungs, and 1.8 per cent. of the livers in 1888-1889, to 1.7 per cent. of the lungs, and 0.5 per cent. of the livers in 1892-1893; in sheep they fell from 1.4 per cent. of the lungs and 0.9 per cent. of the livers, in 1888-1889, to 0.9 per cent. of the lungs and 0.3 per cent. of the livers in 1892-1893.

The fewer slaughter-houses we have the easier it will be to control the diseases. In a tour of inspection I made not long ago, selecting two different States, I found twenty-nine towns, varying from about 100 to 1600 inhabitants, were provided with sixty-nine local slaughter houses. Sixteen of the towns had two slaughter-houses each, eight had three each, two had four each and one had five! Thus these twenty-nine towns provided sixty-nine centers of disease for the surrounding area.

Segregate the slaughter-houses, compelling all the butchers of each town to do all of their killing in a given inclosed area. The slaughter-house could best be built by the city, stalls being let to the butchers for slaughtering purposes.

This suggestion will naturally not meet with the approval of all butchers. The objection will be made that they have money invested in slaughter-houses and that any change will mean financial loss to them. To this I would reply that all or nearly all local slaughter-houses are frame buildings which are not of much value; they are cheaply built and poorly arranged; they represent an infinitely smaller investment than the stock of neighboring farmers, or the lives of the inhabitants, computed at the legal value, and the temporary loss to be sustained by the butcher will be infinitely less than the continuous loss sustained by neighboring farmers and by the community at large. Furthermore, these numerous slaughter-houses are menaces to public health, and under these circumstances a small financial loss to a few individuals can not be taken into consideration.

Another objection that will be made by the butchers is that while the segregation of the slaughter houses would reduce the number of centers of infection, it would not reduce the amount of infection in a given district. To this the reply is, that the objection is more apparent than real, since a given amount of infection in a restricted area is more easily controlled than the same amount of infection scattered over a large area and in different localities.

Objection will also be made that this segregation of the slaughter-houses is an innovation, an experiment, a scientific theory which is not practicable. The reply to this is, that while it is an innovation in this country, it has been tested and found satisfactory in other countries where practical experience has borne out scientific theory, and where the plan has been shown to be entirely feasible.

Objection may be raised that one butcher does not care to be subjected to having his business open to the gaze of other butchers. This objection answers itself. There undoubtedly are butchers who would object to having other butchers see the class of stock they kill or raise, and the sooner the health authorities exercise some control over these dealers the better.

My second suggestion relates to the director of the proposed municipal abattoir. If the slaughter-house is placed under city control, the natural tendency among certain people will be to claim that patriotism calls for the appointment of the director according to his political pull. I would modestly suggest that an unsuccessful blacksmith, or barber, or a physician, dentist or druggist, who has failed in your State examination, is hardly the person to be appointed director of a municipal

abattoir, notwithstanding his political pull. In this matter of public health we are dealing with life and death, and we must have a man equal to the position. Personally, I believe that the man appointed should be a veterinarian, and should be ex-officio a member of the local board of health. And by this word veterinarian I do not mean a quack horse-doctor, but rather a well educated and scientifically trained graduate of a reputable school, and besides that a man of experience in gross pathology and meat inspection. The scientific meat-inspector can render public service in the prevention of disease among men and livestock to a degree scarcely dreamed of by non-technically trained laity.

My third suggestion is on behalf of the butcher. While I believe every butcher sins more or less in selling meat which he ought not to sell, he unquestionably does so unintentionally and innocently in many cases. He is not trained in pathology and does not understand the exact nature of all he sees. He may even tell his customer that this or that meat is not an especially good article, but it can not be expected that he knows the danger connected with lesions which even few physicians would at first recognize.

The proposition that diseased meats which are dangerous as articles of food should not be allowed on the open market, is one which will receive universal support from all sanitarians and also from the thinking public. The question however arises as to the classes of diseased meats and the stages in these diseases that justify their condemnation, or that justify their sale, and the method of their disposal if condemned.

In some foreign cities regulations exist, or have existed, compelling the burial or cremation of meats affected with certain diseases. To such extreme measures I am opposed, and this for several reasons. Such destruction by burial or by burning is in itself an expense. It also results in a total and unnecessary loss of the carcass. Again, the burial of a diseased carcass, unless buried in quicklime or other destructive material, does not meet either the practical or the theoretic requirements of destruction of diseased material. Take trichinosis, for instance. In some places the carcasses of trichinuous hogs have been buried by order of the sanitary officials. After this has been done, the owners of the carcass have disinterred the hog and it has been used for food. This has happened a number of times in Germany, one case being reported within less than a year past. Even had these human rats not disinterred the body and fed it to their friends and customers, the grave would have been accessible to rodents, such as rats, field mice, etc., which would not hesitate to feed upon the carcass, and thus become infected with the disease, resulting in a possible (theoretic) ultimate transmission of the disease to other hogs. Finally, I am opposed to this method of alleged destruction on the ground that diseased or partially diseased carcasses can be utilized under certain conditions and restrictions or in certain ways, so that the owner will not lose the entire amount of his investment.

Three methods in particular are open, the method selected being dependent upon the nature, extent or stage of the disease and the facilities at hand. These methods are: 1, utilization as fertilizer; 2, rendering the meats harmless by cold storage, cooking, or preserving, and then placing them upon the market; 3, selling the meats under a declaration of their character.

There is no parasitic disease known which will withstand the degree of heat used at the large abattoirs in the preparation of fertilizers. "Tanking for fertilizers" is therefore an absolutely safe method for the disposition of condemned meats, no matter how serious the infection is, or to what extent the disease has progressed.

In connection with certain bacterial and parasitic diseases, however, a question arises as to the necessity of condemning to the tank certain diseased conditions. A case of generalized cestode tuberculosis (*Cysticercus bovis*) should undoubtedly be "tanked," but in a very light infection the question takes a different aspect, namely: Can not the diseased portion be cut out and the rest of the carcass be placed on the block? To allow such meat on the market, leaving the consumer to suppose that he is purchasing a first class article, is evidently an injustice to the buyer, for it is by no means certain that all of the parasites have been detected and removed. To condemn a light infection of this disease is, on the contrary, an injustice to the dealer, for there are methods by which the remaining parasites, if any, may be rendered harmless, and in this case the dealer could be saved a part of his loss. To judge between those cases in which the carcass is absolutely unfit for food, and therefore to be condemned, and those cases in which the carcass may be treated according to methods which will destroy the remaining but undiscovered parasites, thus rendering the meat fit for food, is a point upon which the expert meat inspector must decide.

Experiment shows that the parasite under discussion (*Cysticercus bovis*) dies about two to three weeks after the death of its host. Three weeks of cold storage would therefore render a light infection of this kind absolutely harmless, and the meat could safely be placed on the block. With the disease known as pork measles the parasites live for a month, so that more care would be necessary in dealing with it.

Many of the abattoirs voluntarily tank for canning certain meats of inferior quality. The heat to which these meats are subjected is not so great as that used in tanking for fertilizers, but as *Cysticercus bovis* can not survive a temperature of 140 degrees Fahrenheit for five minutes, and as the meats tanked for canning are thoroughly cooked, it may safely be asserted that a light case of "beef measles" would be rendered perfectly harmless by the cooking preparatory to canning. The same applies to cases of trichinosis. The parasite of this disease can not withstand a heat of 70 degrees C. (150 degrees F.) so that if trichinuous pork is cooked until the entire piece has reached this temperature, and assumed a light gray color, the disease is rendered non-transmissible to man.

The parasite of "beef measles" is killed in twenty-four hours by the action of salt solution, and we have found no case where the parasite of trichinosis has been able to withstand four months in the "pickling vats." In both of these cases it must be remembered that it takes some time for the salt to thoroughly permeate the tissues. It would accordingly not be safe to assume that in a piece of measly beef which had been placed in brine for twenty-four hours the parasites had been killed. The length of time necessary to guarantee the result is, of course, dependent upon the size of the piece of meat. A safe rule is to cut the meat into pieces of any length, but not over six inches thick, and leave them in brine for two weeks.

While the large abattoirs have means at their command by which cases of light infection may be rendered non-infectious, the smaller slaughter-houses are at more of a disadvantage in this respect. Cooking and salting would be possible for some, perhaps all of them, while cold storage would often be out of the question. . . . In some parts of Europe certain meats of inferior quality are allowed on the market under given conditions. One of these conditions is that they must be sold in a specially licensed meat stall or counter, known as the "Freibank" or "Finnenbank," where the true nature of the meat must be made known to the purchaser. Naturally such meats are sold at a lower price than the meats offered in open market, thus enabling many of the poorer classes to purchase meat who can not afford to pay the regular prices. Meats which are absolutely dangerous from a sanitary standpoint are, of course, excluded from these special meat counters, and in some instances the law requires that even those meats of inferior quality, which are harmful in some cases, though not dangerous, must be rendered harmless before being sold.

The German system of the "Freibank" practically results in dividing the meats into three classes: 1. Meats which may be sold in open market, good or first-class meats ("gute oder tadellose Ware," of North Germany, "bankwürdiges Fleisch," of South Germany, also called "bankmässig" or "ladenrein"); 2. A second class of meats which may be sold only under declaration of their true character, in many cases only after having been cooked or salted under official supervision ("nicht-bankwürdig," "nicht-bankmässig," "nicht-ladenrein"); 3. A third class of meats which are unconditionally condemned, and therefore excluded from the market. . . . Objections to the "Freibank" have been raised by some parties, but I am unable to see wherein this system is unfair either to the dealer or to the purchaser, for no one is obliged to buy this meat who does not wish to do so, while any one who wishes a cheaper class of meat can purchase it at the "Freibank" with the full knowledge of the condition of the meat he is buying. It is perfectly safe to use the meat when thoroughly cooked, and the dealer is able to economize in his business. I take the decided stand, however, that it is far better to subject all these meats to thorough cooking or other methods of safeguarding before they are placed upon the market.

SUMMARY.

1. A well-regulated system of slaughter-houses is as necessary to the public health as is a well-regulated system of schools to the public education.
2. Every slaughter-house is a center of disease for the surrounding country, spreading trichinosis, echinococcus disease, gid, wireworm, and other troubles caused by animal parasites, and tuberculosis, hog cholera, swine plague, and other bacterial diseases.
3. The important factors concerned in spreading these diseases are offal feeding, drainage, rats and dogs.

4. These diseases may be greatly held in check and in some cases entirely eradicated in two ways: 1. By a reduction in the number of premises on which slaughtering is allowed, on which account it is urged as all important that there be a segregation of the slaughter-houses, so that all the butchers of any given town will be compelled to do all their killing in a common inclosed and restricted area. In abandoning slaughter-houses, care should be taken to destroy the rats, in order to prevent the spread of infection. 2. By regulating the factors concerned in spreading the diseases: *a.* Offal-feeding should be abolished; *b.* Drainage should be improved; *c.* Rats should be destroyed; and, *d.* dogs should be excluded from slaughter-houses.

5. A licensing of slaughter-houses by the State Board of Health and the employment of an assistant State veterinarian, whose sole or most important duty shall be a sanitary supervision of all places where animals are slaughtered for food, are necessary.

6. The appointment on every local board of health of a competent veterinarian, whose duty it shall be to control the class of meat placed upon the block, is urged. All meats should be inspected at the time of slaughter, thus securing for the local consumer the same guaranty that the National government provides for the foreign consumer and for interstate trade.

7. The prohibiting of the rotting of any kind of stock within the premises of slaughter-houses is advised, as are also State regulations to the effect that when a stock animal (horse, of course, accepted) once enters the premises of a slaughter-house it must never be allowed to leave those grounds alive, but must be slaughtered within two weeks' time.

8. In justice to butchers and as a protection to the consumer, I strongly advocate the introduction of the German "Freibank," in connection with every municipal slaughter-house.

SOME PREVALENT DISEASES OF DOMESTIC ANIMALS IN MARYLAND.

Dr. A. W. CLEMENT of Baltimore, read a paper on "Some Prevalent Diseases of Domestic Animals in Maryland." He said: Tuberculosis is very prevalent among the cattle of Maryland at this time. Such cattle should be dealt with in a manner which will protect the public from the possibility of infection. No one appears to have this matter in charge, hence there is no means to prevent the use of the milk from these cows, or the meat when offered for sale by the butcher. When we have so sure a method of diagnosis as tuberculin by which to detect the presence of tuberculosis in cattle, it should be made the duty of some one to take the proper steps to protect the innocent public. Rabies exists in the State to a much greater extent than has been supposed. It is a distinct disease propagated only by inoculation. Hence it can not spread unless introduced by some one animal afflicted with it. Legal enactments should be resorted to which will enforce that kind and character of cure necessary to eradicate the disease. A proper dog law would largely assist in preventing the spread of rabies, since the dog is one of the most active to spread it. Many horses have been killed by a disease said to be cerebrospinal meningitis, but the queer thing about it is that there are no cerebral symptoms or spinal lesions present. It has been supposed that weeds of different kinds had much to do with the disease, but this has not been proven. It is, however, extremely fatal. It affects horses in the stables, in the fields, in winter and in summer; but probably is more prevalent in the former.

In the discussion which followed, Dr. AUGUST STABLER of Montgomery, advocated a law to prevent the spread of tuberculosis, and mentioned instances where cattle evidently diseased were sold in spite of every effort to bring the vendor to a proper idea of the injury he was doing.

Mr. CHAS. HARTSHORNE also of Montgomery, said they had made somewhat of a study of rabies down his way, and could now tell whether a dog is mad or merely indignant. When the former is the case he runs with his tail hanging loosely down; when he is indignant it sticks straight out behind; when he is frightened it clings close between his legs.

Dr. A. C. ABBOTT thought that special licenses for dairymen would aid in the work of inspection and prevent the sale of diseased milk. Every safeguard should be thrown around the milk-supply, as it was liable to produce disease at the fountain head among the children.

Dr. S. S. MAYNARD of Frederick, read a paper on "Hog Pens and Slaughter-houses in Towns." He depicted at some length the dangers to public health from the carelessness with which these were kept; the general filth surrounding them; the wretched condition of the cattle in many cases; the feeding of diseased offal, etc., to pigs, thus conveying more disease through them to other animals. Such a condition should not be permitted. It would be better to have a few abattoirs in place of the numerous miserably kept places in which animals were killed to be made into food for men.

Among those who took part in the discussion which arose on these papers was Mrs. Fendler, an active member of the Woman's Health Protective Association of New York. She gave a history of the excellent crusade in New York City against a badly conducted slaughtering system, and detailed the success which attended their efforts.

At 3 P.M. on Friday the Association again convened, and a paper was read by Dr. W. D. THOMAS of Baltimore, on

SANITARY CONDITION OF THE PUBLIC SCHOOLS OF BALTIMORE.

His attention was largely given to the outhouses attached to each school. Without exception they were found to be most unsatisfactory and deserving of the most severe condemnation. He thought particular attention should be paid to the overcrowding which exists in many of the schools. Rooms arranged for forty pupils are required to accommodate sixty or seventy at the expense of the health of both teachers and scholars. Proper ventilation is not possible in many cases owing to the close proximity of the water-closets, and the methods employed for changing the air in many instances is simply that of lowering a window above the head of some child, who suffers thereby, in many cases admitting the foul air from a contiguous water-closet to so great an extent that it became necessary to close the window speedily. The result of his inspection showed conclusively that the school-rooms are not properly cared for. Floors are washed but three times a year, and inside painting not done until absolutely necessary; as a consequence, many of the rooms have a besmeared appearance. He suggested that an inspector be appointed, not burdened with the care of other buildings to have charge of the sanitary condition of the buildings and surrounding grounds. To these duties might be added the inspection of suspected infected children and to follow cases of disease existing in the homes of pupils.

The subject was continued by Dr. S. J. FORT of Ellicott City, who read a paper on

OBSERVATIONS ON THE HYGIENE OF THE PUBLIC SCHOOLS OF HOWARD COUNTY.

He said: No matter how wide-awake or up-to-date a board may be, the bucolic mind is still apt to think that what was good enough for the children of the past is good enough for children of today. . . . From a hygienic and sanitary standpoint there is not one school in the county in which some fault can not be found and many are absolutely unhygienic in every respect. A searching investigation, made some time since by the State Board of Health, shows the pressing necessity of a complete remodeling of at least one-half of our school-houses, of providing a pure water-supply for every school at present unprovided, a stricter attention to the law requiring vaccination, a closer attention to quarantining children from families in which there are cases of infectious or contagious diseases, and provision for properly disinfecting the walls, floors and furniture of the schoolrooms.

At present, so far as I can learn, the teacher is permitted to have the schoolroom swept or scrubbed and incidentally pay for this service out of his or her own pocket: hence while it is done, sometimes with ordinary soap and water, it is only in rare instances if ever that scientific disinfection is practiced and, however done, the floor is the only part scrubbed, successive generations of children using the desks from year to year, each year adding its collection of nasal discharges, sputum and general filth to those of years gone by.

A single drinking cup, one solitary brush and comb, piece of soap, wash-basin, etc., render personal cleanliness a misnomer and hamper the efforts of the teacher to bring about the condition that is said to be next to Godliness, at the same time helping along the dissemination of skin diseases and parasitic insects, to say nothing of more serious diseases that may thus be carried from one to another.

In making the investigation already alluded to, the State Board sent out a list of questions to every teacher in the county and while not all of them replied, enough answers were received to show the condition of a majority and a tabulation gives results as follows: Eight schools in four election districts are overcrowded; ten school lots in five districts are badly drained; seven schools in three districts are badly ventilated; ten schools in three districts have a bad water-supply; eight schools in five districts have bad outhouses; thirteen schools in four districts do not require vaccination; two schools in two districts do not enforce quarantine.

Our county is also distinguished by being one of nine exempted by law from having more than one privy: a law passed in 1894 providing that every school should have two privies, one for each sex, properly protected from the weather and perfectly private, specially exempting Howard County with eight others, to the shame of the school board that then or ever failed to cry out upon such an outrage on common decency.

Notwithstanding this exemption some of our schools have two privies, but there are many with only one and, as seen by the tabulated returns, ten outhouses are reported as being in bad order.

We have a law providing for teachers' institutes annually, during which meetings the teachers could be instructed by experts in the laws of sanitation and hygiene, and the teachers of Howard County as a rule are far above the average, needing only to be shown the way to respond at once. We have a law providing for meetings to be held at intervals for the benefit of the patrons of the schools, at which the same information should be disseminated, bringing them into closer touch with the school authorities and providing opportunities for discussion of ways and means to perfect the hygienic and sanitary arrangements of the schools; this law is also a dead letter. The excuse given for the supineness of the school board is that money can not be had to work with, but I question whether an appeal to the people would not bring a response in hard cash, just as much as I question whether a parsimonious and non-progressive board is not equally culpable with one that steals the people's money: the former is robbing the children of the tax-payers of their birthright, the right to receive a thorough education and with it to have their health protected by every safeguard known to man, while the other only steals money.

Mrs. DANIEL MILLER of Baltimore read a paper on

AN INSPECTION OF THE BALTIMORE PUBLIC SCHOOLS.

She said: Investigating the public schools was undertaken as part of last winter's work of the Arundel Good Government Club. Our plan was to visit *all* the primary schools and as many more as convenient, resulting in reports from forty-nine buildings, including thirty-six primaries, five grammar, four annex, two colored and two English-German. Of the 137 buildings now in use, 103 are owned by the city and 34 are rented; most of the rented buildings visited were dwelling houses, not only not adapted to school purposes, but totally unfit to be so used. Some of the school buildings, noticeably the *newer ones*, are in excellent condition. In the old buildings, far too many pupils to the air space of the rooms is the rule throughout the schools and in some of the buildings the overcrowding is a positive disgrace. For instance, in Primary School No. 20 102 boys were found sitting on the floor of the teachers' platforms. In Primary School No. 6, 80 children and two teachers were occupying one room, and in Primary School No. 12 38 children in a room eighteen by seventeen feet. In Grammar School No. 10 (where boys occupied the first floor) 300 girls were packed into the second story of an old building composed of eight rooms, about fifteen by twenty feet each. These rooms open into each other with glass partitions and no corridors between the rooms, making them death-traps in case of fire, and impossible to ventilate.

After the overcrowding, the condition of the outhouses seemed the greatest menace to good health. Insufficient accommodation and insufficient separation is common, while close proximity to the schoolrooms and lack of cleaning makes it impossible to open certain classroom windows even in warm weather.

Provision for the disposal of wraps during school hours vary from large and well-appointed cloak rooms to schools having neither halls or corridors (except the outer one, the rooms all opening one into another), consequently cloak rooms are unknown, and in addition to stoves and human beings, the heavy wraps (often damp, sometimes strongly permeated with home cooking) are piled between the children when sitting at their desks or hung many deep on pegs: certainly a most prolific cause for the spread of contagious disease as well as direct danger to children themselves. Seating of school children at desks properly adapted to them is (so far as the committee was able to learn) not considered. Even in the best equipped schoolrooms there is no adjustable desks and no effort seems to be made to adapt desks of different sizes to the pupils, even where these are provided.

The usual means of relieving thirst is from the hydrant in the yard, and through the winter months uncovered buckets of drinking water are brought to the class rooms with one or two cups to a room probably occupied by forty children. In one or two schools only was it found that each child was supplied with its own drinking cup. Buckets of water were also in the rooms for wetting sponges and slates. Is it not feasible to replace this nuisance with some cheap paper and pencils?

As good housekeepers, the committee was deeply interested to find the ordinance for cleaning school-buildings decrees they shall be swept daily and scrubbed three times a year, midsummer, Christmas and Easter. However this ordinance may have originated, the letter of the law is carried out to the present day as only one exception to it was found.

There seems to be an unfortunate proximity in many cases of schools to saloons. One report mentions seven within two squares, another six, still another five.

SCHOOL LIFE AND CHILDREN'S EYESIGHT.

Dr. HIRAM WOODS of Baltimore, read a paper on "School Life and Children's Eyesight." In company with Dr. H. Harlan he had made a plan for the examination of the school children's eyesight. This was adopted by the Baltimore School Board. The examination was systematically made, and in 1895-6 53,069 children were subjected to the examination; of these, 43 per cent. had normal vision in each eye, and 17 per cent. fell below that. During the last session 39,241 were examined, 16 per cent. fell below and 52.5 per cent. had normal vision. There is a necessity of a modified curriculum for children with defective vision, but not too defective to permit their getting an education. The number of these children is not inconsiderable. Subjects of every-day use should be taught in such cases. Books with large clear type should be provided. Otherwise they must grow up in ignorance. They should have three hours for recreation, eight hours for sleep, and yet rise sufficiently early in the morning to reach school without being unnecessarily hurried. Blinding and sick headaches are the result of improper light in the school, or not enough light. This is accompanied by pain in the head and partial blindness. The causes are also often the result of other conditions, hence it needs the most guarded examination to enable one to know just what is producing this trouble. He exhibited forms of desks and chairs to show how often the child is wrongly seated, with the desk too high or too low, not a proper slant, etc., not proper support for the back.

In the evening a joint meeting of the Association with the Medical and Chirurgical Faculty of Maryland was held in Levering Hall, Johns Hopkins University. Subject, the "Sewerage of Baltimore."

Dr. JAS. F. McSHANE, Health Commissioner of Baltimore, read an abstract of his report of the "Sewerage Commission."

The next paper was

THE RELATION OF TYPHOID MORTALITY AND SEWAGE

by Dr. WILLIAM OSLER, professor of medicine in Johns Hopkins University. His text was the trite statement that typhoid fever is the sanitary index of a city. He considered it under three headings. 1. The mortality from typhoid fever has progressively declined with improvement of sanitary conditions. In 1838 in England, 1228 persons died of typhus and typhoid fevers per 1,000,000 living. Twenty years later this was reduced to 918: in 1878 to 306 of typhoid and 36 of typhus: in 1892 only 137 died of typhoid, 3 of typhus per 1,000,000 of living. In London the death rate per 1,000,000 of living was 307 in 1869: in 1892 it was 102. Three factors have been concerned in this extraordinary saving of life, the cleansing of towns, the purification of water-supplies and the introduction of good sewers. 2. The death rate from typhoid fever forms an accurate measure of the efficiency of sewage removal and the pureness of the water-supply. A tabulated statement of the death rate of sixty-five cities from typhoid, during five years, 1890 to 1894, grouped in seven classes, shows in class 1, comprising thirteen cities, the rate was under 10 per 100,000, but contains no American city. In class 7, comprising thirteen cities, the death rate was over 60 per 100,000, and all are in this country except Milan, Cairo and Alexandria. The lesson of several European cities is worth reading. Munich had in 1857, 291 per 100,000 and kept that high until 1865, when there was an improvement in the water supply and a reduction of almost 50 per cent. After the introduction of the new system of drainage the mortality was still further reduced, and in 1887 was only 10 per 100,000 of the inhabitants. 3. Baltimore has a typhoid fever death rate of a fairly well-watered but unsewered town. During the years 1893 94 95 96, 908 persons died of this disease, a yearly average of 227. Prior to the introduction of a good water-supply the death rate was 74 to 80 per 100,000 of the inhabitants, now reduced to about 41. Good water alone is not sufficient, as shown by the experience of the cities of Dantzic and Stockholm. In the latter the death rate from typhoid fever fell *pari passu* with the number of meters of sewers, from 51 per 100,000 in 1877 with 937 meters of sewers, to 17 per 100,000 in 1887 with 65,709 meters of sewers. We may confidently expect with the completion of a good sewerage system the present death rate of Baltimore, about 40 per 100,000, to fall to that of cities of the first class, from 4 to 8 per 100,000 inhabitants. What does this mean in cold figures? That 204 persons died in Baltimore last year of typhoid fever? The loss to a community of a person in the prime of life may usually be placed at \$2000. The total funeral expenses would amount at a low estimate to \$5000. About 12 per cent. of those attacked die, so that the total amount of cases of typhoid fever last year in the

city may be placed at about 2500. The loss in wages at \$1 per day during the illness may be estimated at over \$100,000; nursing and doctor's bills estimated at the low rate of \$25 per case, gives \$62,500, a year's fever bill of about \$575,000 against the city of Baltimore for one disease, a sum sufficient to pay the interest on the most expensive plan presented by the commission. The penalties of cruel neglect have been paid for 1896, the dose of victims for 1897 is nearly complete, the sacrifice will number again above 200. We can not save the predestined ones of 1898, but what of the succeeding years? They will be of the fairest of our sons and daughters; they will not be of the very young or the very old, but the youth in his bloom, the man in the early days of his vigor, the girl just waking into full life, the young woman just joying in the happiness of her home. It is not likely that we can abolish typhoid fever completely, as we have abolished typhus, but we can reduce it to a minimum, and if the experience of other cities is worth considering, this will be effected by the introduction of a complete system of sewerage; and, moreover, the total cost of the plan, however elaborate, however costly, would be fully reimbursed in the course of a few years by the saving of life and of unnecessary expense in typhoid fever alone.

Prof. Wm. K. Brooks of the University, delivered a lecture on the

INFLUENCE OF CRUDE SEWAGE UPON ANIMAL LIFE IN THE BAY.

This was in connection with the adoption of the plan for emptying the sewage into the bay. He gave a description of the oyster and its habits, explaining how it plays the part of a filter, every oyster constantly filtering water through its gills. During this process all organic matter is filtered out of the water by means of the oyster's gills. These microscopic organisms in place of passing through the gills are caught and drawn into the stomach, where they are digested. Very many germs may be found in transit from the gills to the stomach. It has been found that the dumping of sewage in so vast a body of water as the Bay would obviate any danger of contamination through oysters. Many interesting experiments have been made in England to ascertain how long disease germs would live in sea water. It was shown that typhoid fever and cholera germs may live three weeks or more, and may be spread through oysters. The oyster itself is not injured by harboring these germs.

Dr. GEO. H. ROHE of Baltimore, read a paper on

METHODS OF SEWAGE DISPOSAL.

The Doctor alluded to the different points brought out in the Report of the Sewage Commission and said: I have no hesitation in agreeing with the recommendation of the consulting engineers, that despite the greater primary cost of the filtration method, the disposal of the sewage by this method is "the best solution of the problem for all time." Surely the successful experience of the City of Berlin with its 1,800,000 inhabitants is an object lesson worthy of consideration. The Commission has shown, that land in abundance and of the most favorable character for the disposal of sewage, can be obtained within eight miles of the city. The cost of this land as estimated is only about 65 per cent. of that paid by the City of Berlin. With the more scientific construction of sewers now possible, and the exclusion of all storm water, the success of the disposal of the Baltimore sewage by filtration should be much greater even than it has proven to be in Berlin, Paris, or any other community where the method has been adopted.

The estimates of cost, made by the consulting engineers and the Commission, are merely approximative. I am inclined to the opinion, however, that the receipts estimated from the selling of crops from the filtration field in the Baltimore system are fixed at too low a figure entirely. The estimates allow for an income of only \$3 per acre from the sewage fields. In 1887-88, the sewage farms of Berlin were partly managed by the municipality, and partly rented to market gardeners in fields of two or three hectares (five to seven and a half acres); the rent obtained was on the average 200 marks (\$50) per hectare. The portion of the sewage farms managed by the municipality returned an income nearly the same, there being only ten cents per hectare difference in the receipts between the fields managed by the municipality and those rented. It has been found that not only in Berlin, but in Paris, in Dantzic, and in numerous towns in England, the rental value in sewage farms has constantly increased. I have therefore no hesitation in saying, that the greater primary cost of the filtration system over the dilution system would be to a considerable extent offset by the increased value of the land used for filtration. But it seems to me, that the adoption of the dilution project would be, as it has been in nearly every instance where the conditions were similar to, or approached those in and

around Baltimore, an experiment likely to result in failure. The filtration of sewage, on the other hand, is not an experiment, but has been always, where adopted, a permanent and final solution of the problem.

Prof. W. H. WELCH of Johns Hopkins University spoke of the relation of sewage to public health. He considered the soil the place which sooner or later all organic matter reaches. It is one of the greatest laboratories in the world, but is only capable of doing this work to a limited extent. Among the dangers from contaminated soil are the gaseous emanations from polluted ground. Another and very serious danger is that of polluting the drinking water. There are various ways in which disease-producing germs can reach us from a contamination of the soil. Typhoid fever, cholera and the diseases of infancy thus almost invariably result. Cholera frequently attacks cities without a proper system of sewage, but has never been able to gain a foothold in cities that are well sewered. Pure water and good sewerage enable a city to defy cholera, etc. Health statistics everywhere give the practical results of a purification of the soil by sewerage. His remarks were well illustrated by a number of charts showing the relative rates of disease and mortality in cities as they were more or less well sewered.

Dr. JOHN S. FULTON closed the discussion with a paper entitled "Will it Pay?" He argued that the expenditure of the amount of money required, would be economic and wise. Cholera cost in 1884, Italy \$7,680,000. In 1878, yellow fever cost the United States \$100,000,000 and 15,934 lives. The annual tax by typhoid fever is \$527,250,000. Typhoid mortality in sewered cities is to that in unsewered cities as 1 to 4.5. He explained the cost of sickness and death from this disease, the loss not only of lives, but time and general health to those afflicted and the loss to the State, and showed that Baltimore would save annually \$1,102,215 by reducing the typhoid fever alone to the lowest possible point. This is an annual visitant, not, like cholera, an occasional one. The introduction of a proper sewerage system would positively enable this reduction to be accomplished. At the same time other forms of disease would be reduced and the general rate of mortality be correspondingly lessened.

The subject having been concluded, Dr. G. LANE TANESYHILL, Chairman of the Committee on Health of the Commissioners of the Public Schools of the City of Baltimore, spoke in defense of that committee and called the attention of the Public Health Association to the fact that the members of the school board are not responsible for the insanitary condition of the school-houses, but that that duty devolves on the health commissioner and the inspector of buildings. He outlined the work already done toward alleviating existing conditions and the difficulties accompanying such work, and said: "How to maintain an educational system that fits perfectly public needs is one of the most important problems that confront the municipal reformer," but to take a dark and ill ventilated, if at all ventilated, old building, and introduce modern sanitary conveniences and improvements is a task in this city that may well puzzle the best informed sanitarian. Many of these antiquated buildings are so deficient in the proper provision for light that Drs. Harlan and Woods, the oculists appointed by the school board to inspect the eyes of the children, were compelled to condemn many of the rooms as unsuitable places for study. Even the proper provision for the general health of pupils at this, the most important period of their young and growing brains and bodies, can not in many of these buildings be made. The contracted space allotted for the yards was apparently only equaled by the contracted appropriations, when many of these buildings were erected. The committee has found it to be impracticable to supply the crying need, "enforced ventilation" in these buildings on account of their faulty construction. This system is the only system now advocated by those who are considered experts in this branch of science: it includes the use of fans by which moderately warmed air is forced into the school-room in such quantities as to give to each pupil 1800 cubic feet of air per hour to breathe. One member of the committee has seen this system work admirably in New York City. It is highly commended by school commissioner Buckley of that city. In Baltimore we have it in three or four buildings.

In conclusion, Dr. Tansyhill remarked that during the seven or eight months of the existence of the new school board, many other questions had been considered by the committee on health and the board in general, such as a more sanitary manner of supplying drinking water to the pupils, possibly the use of a spigot in each class room; the changing of desks to suit the height of the children by individual measurements; a traveling inspecting committee is now in other cities examining the kind of desks most nearly adapted to the present necessities; the text-book committee had ordered the unclean slates to be dispensed with and have substituted the unglazed paper pads:

the floors have been more frequently washed; the urinal troughs flushed, the privies ventilated as well as possible, and two sanitary inspectors are continually engaged in looking after the immediate wants of the schools as rapidly as is in their power. The over-crowding, the proper lighting, the sufficient ventilating, the proper removal to a sanitary distance of the privies, and the prevention of the proximity of the saloons can best be remedied by a liberal appropriation by the city council for the building of modern sanitary schoolhouses with ample yard space. Today this city is in urgent need of at least fifty such buildings.

PRACTICAL NOTES.

Dyspepsia with Flatulence.—Tincture gent.; tr. valer.; tr. nuc. vom. ãã 4.0; chloroform, xx-xl gtt. Ten to twenty drops in water before meals.—*Memorabilien*, January 18.

Sublimate in Erysipelas and Meningitis.—Voskressensky reports much better results with sublimate in erysipelas than with any other remedy; sixty-five cases. The surface was painted with an alcoholic solution at .5 to 1 per cent.—*Nouv. Remèdes*, January 24.

To Avoid the Trickling of Serous Fluid after Abdominal Paracentesis. Gumprecht applies a small cotton tampon and covers it with a couple of folds taken up in the skin, held in place with adhesive plaster. The skin can be painted first with collodion if desired.—*Therap. Monatsh.*, 1898, No. 2.

Menthol in the Treatment of Varicose Ulcers of the Legs.—Simionelli recommends a powder composed of fifty parts of chlorid of sodium and five parts of pulverized menthol. Both substances should be in the form of an impalpable powder, and intimately admixed.—*Medicine*.

For Gastric Cough and Hiccoughs.—A. Robin recommends a teaspoonful every hour of the following, never taking more than a third of the whole during the twenty-four hours: Potassium cyanid, 5 centigrams; syrup of morphin and syrup of orange flowers, ãã 75 grams.—*Semaine Méd.*, February 16.

Subcutaneous Injection of Quinal.—Stofella recommends for this purpose quinin muriaticum, which dissolves in water heated to 40 degrees C. (two grams to 10 c.c. water at 40 degrees). There is no local reaction if antiseptic precautions are observed. Dose: One Pravaz syringe, equal to 0.2 quin. mur.—*Wien. klin. Rundsch.*, January 2, *Vide JOURNAL*, January 29, page 268.

Aspiration Treatment of Ingual Bubó.—R. Hahn reports 70 per cent. out of 200 cases cured by aspiration of the contents of the bubo, requiring no further operation (75 per cent. with one single aspiration). The cavity is then rinsed with salt solution and a gauze pad applied, held with a zinc plaster and compressing bandage outside to reduce the distended skin and prevent the accumulation of more pus. If the deep-lying glands are found to be involved total ablation is necessary, but otherwise aspiration will be found sufficient.—*Mitth. a. d. Hamburg. St. krk. anstalten*, i, 3.

Mechanical Process to Favor the Expulsion of Sputa.—In cases of myelitis in which the muscles of the thorax are paralyzed, bronchial complications prove exceedingly distressing, as expectoration is difficult. Reusner describes a method of relief which can be easily taught to the attendants, and has proved most effective in his practice. The aim is to reinforce the diaphragm and abdominal muscles in their effort to expel the accumulations in the bronchi. The patient on his back, bladder emptied, the attendant on the right side, the latter applies his right hand to the abdomen, pressing progressively downward into the small pelvis, stretching the skin. The left hand is then applied outstretched on the hypogastrium, the pressure sufficient to enable the pulsations of the aorta to be felt. The compression is continued as the patient coughs, and relief is immediate.—*St. Petersb. Med. Woch.*

Prevention of Contagion of Measles.—Ausset asserts that measles is contagious during the pre-eruptive stage, but that contagion can be prevented then and later by destroying the germs in their stronghold, the mouth, nose and eyes. He uses for the purpose copious irrigations twice a day with two quarts of fifty per thousand solution of Labarraque's solution, with boricated water for the eyes, although he admits that a spray of mentholized oil might be equally effective. Six cases thus treated at the hospital were not followed by any contagion, although they were not isolated in the least, but mingled freely with the other children.—*Nord. Méd.*, v, 81.

Formalin Disinfection of the Field of Operation.—None of the disinfectants in vogue reach and destroy the germs that have penetrated below the surface of the skin, and yet these are a frequent cause of infection. Professor A. Landerer reports that he has succeeded in securing absolute bacteriologic asepsis with a 1 per cent. solution of formalin applied on an air-tight compress, after the usual preliminary toilet, and left from twelve to thirty-six hours, changing once or twice. The vapors penetrate and kill the germs in their remotest strongholds, and perfect prima intentio is secured.—*Cbl. f. Chir.*, February 26.

To Locate Foreign Bodies by Radiography.—Morizes secures extreme accuracy with four small adhesive discs of lead. The patient placed between the tube and the screen, one of the discs is placed over the spot where the foreign body is seen, and another on the side toward the screen in a straight line with the first disc and the foreign body, so that all three cast but one shadow. The patient is then turned at an angle and the two other discs are applied in the same way on another straight line, also passing through the foreign body. The intersection of the two lines locates it with precision.—*Presse Méd.*, February 12.

Improved Local Anesthesia.—The Oberst method of anesthetizing fingers and toes, described in the *JOURNAL*, February 26, page 496, has been found equally applicable to operations involving the entire hand or foot, and is urgently recommended by Kraske-Manz in the *Cbl. f. Chir.* of February 19, who report several cases operated, including some serious cases of metatarsal caries, requiring an hour's work, with the removal of the toes, metatarsal and cuneiform bones. The blindfolded patient conversed quietly, feeling nothing of the operation, but two to three minutes after the ligature had been removed, could feel the slightest touch on the toes. A 1 per cent. solution is used; 0.02 to 0.025 gram, to 0.05 to 0.06, but Manz suggests that possibly a stronger concentration might shorten the fifteen to twenty minutes waiting time. He adds that possibly the compression of the nerve, stagnation of the blood, etc., may all be factors in the anesthesia secured, which he believes is even applicable to an entire limb.

Operations to Remove Syphilitic Cerebral Tumors are justified, Schlesinger asserts, when the tumor is stationary and does not yield to antisyphilitic treatment, easily accessible and presumably of small extent. An operation is especially indicated if the tumor grows worse, unchecked by specific treatment, or if Jacksonian epilepsy develops, even if the tumor retrocedes. He considers it counter-indicated by the presence of basal or extensive spinal syphilis, extreme weakness, or amyloidosis. He describes a case operated on with the rare symptom of isolated paralysis of the hypoglossus unaccompanied by paralysis of the facialis. The gumma was in the dura, on the left central convolution, the size of a "gulden." During the removal the right facialis twitched and the right half of the thorax did not join in the act of respiration. There was hernia of the brain later through the drain opening, and right hemiplegia, which gradually subsided. He concludes by urging the necessity of sparing as much of the cortical tissue as possible, to prevent permanent paralysis.—*Wien. klin. Woch.*, January 27.

THE

Journal of the American Medical Association

PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

Per Annum, in Advance	\$5.00
Foreign Postage	1.75
Single Copies	10 Cents.

On requesting change of address, give *old* as well as new location. Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, 100 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, MARCH 26, 1898.

SOME MEDICAL QUESTIONS OF A POSSIBLE WAR.

Now that war talk is rife and it seems a little more than merely possible that the "dogs may be let loose," to use a well worn figure of speech, it is in order to consider certain medical problems that are inevitably suggested by the state of affairs. If we are to be rushed into a war with Spain at the very close of the healthy season on the island of Cuba, it would appear probable that hostilities will either have to be limited to the sea or if carried on by land will be complicated with some very serious sanitary questions, at least during a portion of their continuance. What naval warfare will be with modern ships and guns is very largely a question for the future to decide, the little experience gained by a single engagement in the China-Japan struggle hardly being enough for any one to generalize from to any great extent. One thing seems probable, that is that the mortality will be either slight or very great, that modern naval iron-clad vessels will be very likely to either fairly protect their crews or prove their coffins. There will not be, or should not be the splintering of wood that in the old-fashioned oak-built ships contributed so largely to the minor and sometimes the major casualties of a naval engagement. There may be, however, more than an equivalent in flying bolt heads and rivets and splinters of steel, and the danger of fire where there is anything combustible to burn is enhanced by the tremendous heat produced by the impact of modern projectiles on resisting armor. There has been only one person who has given a graphic account of his experience in a large modern ironclad under perhaps exceptional conditions of exposure to the fire of modern high powered artil-

lery, and he shortly after died, insane apparently from the effects of the shock to his nervous system. This is a factor also to be reckoned with; it may be not a very serious one on the whole, but this also is one of the medical problems the future will have to decide. Judging from the war game as played by naval officers in their schools of instruction in naval tactics, the anticipated ratio of casualties in loss of ships and lives must be very large.

It is not, however, alone in the matter of great-gun performances that we meet with questions of medical interest; the small-arm wounds in a future war may also present us with some new experiences and raise new questions for military surgeons and sanitarians to consider. It is well known that nearly all civilized nations have within the last few years reduced the caliber of their military rifles so that at the present time it is hardly greater than that of the despised "22" pistol, of which a Western pioneer remarked that if any one shot him with it and he ever found it out he would give him a good thrashing. The modern steel-coated bullet has within certain ranges a tremendous effect on certain parts of the body, but in a very large proportion of cases, probably a majority, the immediate effects of the wound it produces are slight. In a strike riot in England not very long ago a miner was shot in the fleshy part of his leg and was entirely unaware of it till, after all was over, he felt a slight irritation that led him to realize that his limb had been completely penetrated by a bullet. The English troops on the Indian frontier found the Lee-Mitford bullet altogether inefficient to stop a charge of fanatical mountaineers, and learned to make them more effective and infinitely more deadly by filing off the steel point. The Indian government taking the hint, invented the Dum-Dum bullet with a soft point which strips off its steel cover and makes a fearfully ragged wound, and is virtually an equivalent to the explosive bullet prohibited by the Geneva convention. Russia is said to have recently adopted a similar projectile, and if this becomes general the wounds of future wars will be more formidable than ever before. The English government seems to be aware of this fact, and has devised a bullet to obviate some of the objections that would be surely raised were she to introduce her Dum-Dum projectile in any conflict with a civilized nation. It is steel cased throughout but has a cup-shaped depression instead of the soft point; it is said to "set up" a little and sometimes split its casing, but this, it is claimed, is a very different thing from the effect of the Dum-Dum projectile or of explosive bullets generally. What Russia will do is yet to be seen, but her reported adoption of the soft-point bullet is a relapse toward barbarism, and if allowed to go without protest will do much to render nugatory all the humane regulations that have been adopted by international agreement to mitigate the

horrors of war. Even the proposed English "Mark III" bullet suggests strongly a modified "express" projectile intended to make up for the small caliber and to aggravate the effects on the victim. It is a serious question whether there ought not to be a new Geneva convention to re-regulate these and some other matters, when civilized nations seem to be trimming their course dangerously near the limits of savagery.

In any case military and naval surgeons of the next war, whenever it may be, will have to face some new problems. The effects of modern projectiles, and the care of the wounded in naval actions, are two of the most obvious of these, but perhaps others as yet unforeseen may arise that will sink these into comparative unimportance.

In the question now at issue in a case of hostilities the sanitary problems on the Island of Cuba will be many and full of interest. The march through Spain from Cordova to Madrid will no doubt furnish much material of interest for the medical historian.

SEXUAL DIFFERENTIATION AND THE PROCESS OF FERTILIZATION IN THE HEMATOZOA.

A brilliant investigation into the biology of certain hematozoa infecting several species of our American birds, especially the common crow, carried on in the clinical laboratory of the Johns Hopkins Hospital, by MACCALLUM and OPIE, and recorded in detail in the current number of the *Journal of Experimental Medicine* (Volume 3, No. 1, 1898), has lead MACCALLUM to make certain observations upon the sexuality and the sexual processes of these parasites which promise to be of far-reaching importance in solving the problems surrounding these biologic phenomena in various hematozoan species, including the organisms of human malaria. The three papers in which these writers describe their studies in avian malaria are valuable contributions to the comparative pathology of hematozoan infections and are well worth careful consideration. The balance of the work is, however, eclipsed in MACCALLUM's second paper ("On the Hematozoan Infections of Birds," *loc. cit.*, pp. 117-136) which contains the account of those processes interpreted as sexual in character.

In patiently studying the various forms presented by *Halteridium* (the most common species in crow's blood) MACCALLUM differentiated two distinct kinds of intra-cellular parasites, a granular and a hyaline variety. It was found that the granular forms never became flagellated, while the formation of flagella was constant in the hyaline bodies. The process of flagellation was carefully watched in the hyaline forms, in which four or more of these motile appendages were suddenly projected from the body of the spherical mass after it had burst from the confines of the enclosing red blood corpuscle. As other observers

have noted, the author also found that the flagella ultimately became detached from the mother cell and swam about freely in the blood plasma. Pondering upon the phenomena presented by the varying forms of this parasite the idea that some of them might signify more than mere polymorphism finally led to the observation best described in the author's graphic language: "Two forms lay at some distance from one another separated by plasma and a few corpuscles. The granular form happened to escape from the corpuscle first and lay perfectly quiet beside the free nucleus and the shadow of the corpuscle. Soon the hyaline body, becoming greatly agitated, burst from the corpuscle and threw out active flagella, which beat about for a few moments and finally tore themselves loose. Then came the acme of the process. One of the four flagella passed out of the field, but the remaining three proceeded directly toward the granular form, lying quietly across the field, and surrounded it, wriggling about actively. *One of the flagella, concentrating its protoplasm at one end, dashed into the granular sphere, which seemed to put out a process to meet it, and buried its head, finally wriggling its whole body into the organism, which again became perfectly round.*" This process was repeatedly verified by the author and by other workers in the Johns Hopkins Hospital, among whom may be mentioned WELCH, THAYER, and BARKER.

It is scarcely possible to contemplate the picture thus accurately drawn by MACCALLUM and not approve in his view that the whole phenomenon is a sexual one, that the granular parasite is the female and the hyaline the male organism, that flagellation is a form of spermatogenesis, and that the final act is nothing more nor less than a sexual fertilization. The only wonder is, now that the whole matter is so lucidly set before us, that the true interpretation should have been so long delayed. It is, however, a matter of patriotic pride that this important discovery should have been made by an American student of medicine, working in an American laboratory.

Since completing his studies upon the avian hematozoa, MACCALLUM has been so fortunate as to discover, in a case of estivo-autumnal malaria in a woman, essentially the same process as was noted in the crow's blood. The malarial crescents were seen to become spherical, one form flagellating, the other remaining quiescent. The flagella were thrown off, and swarming about the quiet sphere the act of fertilization ensued essentially like that noted in *Halteridium*.

Thus it seems that we are at last to have set at rest the mooted points in the biology of the malarial hematozoon which have centered about the crescentic and flagellate forms of the parasite. Naturally these intensely interesting investigations have not disposed of all the problems in the life history of the hematic

sporozoa, but a new impulse has been given which can not fail to be fruitful in its results.

These very important researches furnish another instance of the value of comparative pathologic and experimental methods in connection with the investigation of human diseases.

POST-GRADUATE LECTURES AT HOME.

Many Eastern medical societies have adopted a new plan of increasing their membership and the interest in the meetings. Once a month, or at longer intervals, they invite some leading physician or specialist who has become expert on some topic to give them a lecture, of an hour or less, and then resolve themselves into a general meeting, in which each one becomes a tutor, or inquirer. These are called post-graduate courses at home, where the lecturer comes to the physician, and are becoming very popular in many sections. Prominent medical men, who have made a special study of some topic, are pleased to address medical societies on their favorite themes. As a gratuity their expenses are paid, and they are entertained by the society. The society in this way is enabled to hear the best men and the most advanced studies along new lines, at a trifling cost, and the society becomes the center of new interest, in which all participate. Physicians in Philadelphia have been very generous, and encouraged the country and outside city societies to invite them to their meetings. The result has been very helpful to both the society and the lecturer. Boston medical men have been prominent for years in accepting all invitations of this kind and many Eastern societies boast of having heard at home all the leading medical men of Harvard and other Boston schools. New York and other large cities, have not been so prominent in this field, probably because the country and inland societies, have not the same interest. As an example of the practical working of this new feature of society work, the following is given. The B. city society, nearly a hundred miles from Boston, had six lectures in 1897, from leading physicians in Boston and elsewhere. Two were surgical topics with illustrations of cases; two were on therapeutics, new remedies and means of treatment; one was on rheumatism; and the other on fevers. The society paid, in traveling expenses and entertainment, \$81 for these lectures, and, as the membership was over one hundred, the individual expense was less than a dollar each. The lecturer had an opportunity of addressing a class of practical hard-working men at their homes, enlarging his acquaintance, and usually securing consultations, and above all having a good opportunity to test the value and acceptance of his personal views and teachings. The society also had the pleasure of hearing the leaders in the different lines of study, and of having some measure for comparison of their own attainments. The results have been an in-

creased interest in the society meetings, and a larger attendance with more care in reporting cases, and better papers read. Some of the subjects have caused a great deal of study and dissensions. The lecture on rheumatism was followed by two interesting meetings on this topic.

This is clearly a most practical advance for all local medical societies, and can be followed up almost indefinitely, with the best results. The tendency to egotistic provincialism would be checked, and each society would have new interest to gather and exchange experience.

Nearly all the leading men in the profession would take pleasure in meeting local societies, and giving them the result of their work. It would be far more practical for all medical men to have lectures on their daily work, and become familiar with the advanced studies of leading men, than to subscribe to literary lectures and concerts. Every society of twenty or more members could secure four or five most practical lectures during the winter, at a cost but little more than an ordinary ticket to the theater. Not only the society but each individual would receive great personal advantage from it.

CONCERNING THE PARATHYREOID GLANDS (SANDSTRÖM), OR THE EPITHELIAL BODIES OF THE THYREOID (KÖHN).

The presence of isolated glandular bodies in the neighborhood of the thyreoid gland has long been known. Up to the year 1888 all such bodies were described as accessory thyreoid glands, or as masses of lymphadenoid tissue. By accessory thyreoid glands are to be designated nodules of thyreoid tissue which at some time of development became separated from the main part of the gland, but still appear to be structurally similar to it. The accessory thyreoid glands are inconstant as to occurrence, and are marked by great uncertainty as to position. They have been found at all levels, from the superior hyoid region to the aortic arch.

The parathyreoid gland is a term applied to independent structures remarkably constant in number and position, which at no stage correspond in structure to the thyreoid gland, and which appear to have a function of their own.

These structures, although in all probability noticed by previous observers, as for example VIRCHOW, were definitely discovered by SANDSTRÖM in 1880,¹ who found that man and several other mammals possessed small epithelial glandular organs near or in the thyreoid. In man he described two parathyreoid glands on each side on the posterior surface of the lateral lobes, near its lower margin, one above and one below the inferior thyreoid artery. They were invariably separated from the thyreoid by a layer of connective

¹ Upsala Läkareforeningens Förhandlingar, 1880.

tissue. The histology of these bodies varied somewhat, but it tended to conform to one of the three following main types: 1. A condensed mass of epithelial cells, traversed by a capillary network; 2, a cellular reticulum, in the meshes of which were blood vessels and connective tissue; 3, small follicles in a connective tissue framework. D. A. WELSH² has been able to confirm these observations as far as they relate to the human parathyreoid, and he emphasizes strongly the position and accuracy which characterized SANDSTRÖM'S earliest description of these structures in man.

SANDSTRÖM ventured the conjecture, based upon purely anatomic reasons, that the parathyreoids were embryonic remnants of the thyreoid, destined to form fresh thyreoid tissue when required.

In 1895 KOHN³ published an extended study of these glands in the cat and other animals. He made the important addition to SANDSTRÖM'S work that there are constantly present two parathyreoid glands on each side in the cat, dog and rabbit. Previous observers had recognized only one on each side, and the significance of KOHN'S work is therefore at once obvious, because these animals were the ones chiefly employed for experimental research. He insisted that they are structures morphologically and functionally independent of the thyreoid, and he therefore proposed that they be called the epithelial corpuscles of the thyreoid, distinguishing them further as external and internal according to their relation to the lateral thyreoid lobes. L. R. MÜLLER⁴ in 1896 examined the thyreoid and adjacent glands in twenty-two cases in man. His results agree in the main with those of KOHN, but he states that he could not estimate the frequency of their occurrence in man as he found they were easily overlooked.

It has long been observed that various species of animals present striking and unaccountable differences after extirpation of the thyreoid, and this may occur even in the same species. It was thought that these variations corresponded to differences in metabolism in different animals. Flesh-eating animals seemed to suffer most acutely, while the herbivora suffered less, the omnivora occupying a middle position. In 1891 GLEY⁵ began the publication of a series of papers in which he offered a different explanation. He pointed out that in the rabbit the external parathyreoid is quite distinct from the thyreoid and situated about .5 cm. below it, whereas in the dog the parathyreoid was closely connected with the thyreoid. He investigated the effect of removing both the thyreoid and the parathyreoid in the rabbit, and out of sixteen rabbits only two survived beyond a week. The remaining fourteen showed a rapid train of symptoms and fatal result. By the end of 1893 GLEY had performed complete thyreoidectomy in fifty-five rabbits and only

twelve survived. He then showed that in some animals, even the dog, it is possible to remove the thyreoid and leave the external parathyreoids intact. He describes this delicate operation in ten cases, and of these only two died. Subsequent removal of the parathyreoids in the same dogs led to their rapid death. Since that time these results have been contradicted by some investigators, supported by others. Among the more important of the researches bearing upon this point may be mentioned those of VESSALE and GENERALI,⁶ who removed all four parathyreoid glands, leaving the thyreoid *in situ*. They performed this operation on ten cats and nine dogs. In the cats nine died before the tenth day, after suffering from the characteristic symptoms ordinarily observed after thyreoidectomy; of the nine dogs all died within eight days.

It may be concluded that at the present time no definite statement can be made concerning the functional importance of the parathyreoid glands. Experimental physiologists are still hard at work attempting to demonstrate the relation of the functions of the parathyreoid to the thyreoid body. In the meantime it is well to bear in mind the existence of these peculiar epithelial bodies, now that the study of the thyreoid and other ductless glands is attracting so much attention, because it may be found that these bodies, which are constant, embryologically and structurally different from the thyreoid, may have important functions, the exact nature and the relations of which to those of the thyreoid are as yet not understood.

THE WEEK IN CONGRESS.

The sanitary bills have been up for consideration in the Senate. Senators SEWALL of New Jersey, VEST of Missouri, and others took part in the debate. Senator SPOONER on the 16th submitted anew his bill, this time, in order that it may be properly reached, as an "Amendment" to the CAFFERY bill, which action gives it place equal to that of the committee's amendment, which, as will be remembered, struck out all after the enacting clause, etc., etc.

The Marine-Hospital lobby have been active, as also the Mississippi auxiliary, with Acting Assistant Surgeon ROBBINS, M.-H.S., of Vicksburg, at the fore in the interest of the CAFFERY bill. Dr. DOTY, Health Officer of New York, and Dr. WINGATE of Milwaukee, Chairman of the ASSOCIATION Committee, have also been present much of the time, and have advocated the passage of the SPOONER bill, which has daily gained friends as its scope and extent become better understood. Let us understand that the CAFFERY bill is a quarantine bill, and nothing more; the SPOONER bill is a broad sanitary bill commensurate

⁶ Archives Italiennes de biologie, 1896.

with the importance of the subject and the great interests involved. The latest information we have received is, that the CAFFERY bill is practically dead, but our friends must keep pounding its corpse. Then there will be no question about it.

CORRESPONDENCE.

The Serum Treatment of Tuberculosis.

ST. LOUIS, MO., March 21, 1898.

To the Editor:—I have read with great interest Dr. Waxham's "Report of Cases of Tuberculosis treated with Antiphthitic Serum, T.R. (Fisch)." It is well that all sides of this subject should be presented, as only by the collective investigation of numerous observers working independently, in different places, and under diverse conditions, can any satisfactory decision be arrived at. With that end in view, Messrs. Milliken & Co., have been consistent in impressing on all users of the serum (Dr. Waxham himself not excepted), their desire that reports of cases should be made to the medical press, whether the results be "good, bad, or indifferent." While reports favorable to the serum can not fail to be gratifying, those of failures are equally important, as a means of drawing attention to sources of error on either side.

On reviewing Dr. Waxham's cases, it appears to me a very good thing that he has published them, since they serve as a good text wherefrom to preach more efficaciously what has been laid down *ad nauseam*, viz., that so far as our present knowledge goes, no good whatever can be with any confidence anticipated from the use of the serum in cases in the third stage of the disease, nor even in the late second stage, especially if they show mixed infection.

Now, in no case does Dr. Waxham state whether the examination of the sputum showed the presence of other micro-organisms than the tubercle bacilli in any appreciable numbers; but it is a fair inference from the clinical reports, notwithstanding the absence of temperature records, that there *was* mixed infection in cases 2, 3, 4, 5, 6, 7, 9 and 10; while not a single case is in the first stage, and only No. 8 (apparently), and possibly No. 1 in the second. So far therefore, from their being, as Dr. Waxham states "fair ones with which to judge the value of treatment," they are nearly all excluded *ab initio* from that category.

In proof that this is no *ex post facto* objection, I may state that I have recently returned from a tour of hospitals in the northeastern States, where I have had the privilege accorded me in many of them of selecting for experimental treatment with the serum the most suitable cases available. I am sure that these members of the visiting staff, say of the Massachusetts General, the Carney and the City Hospitals in Boston, the Montefiore Home, the Columbus, City and Seton Consumptive Hospitals in New York, with whom I come into contact, will bear me out from their own personal knowledge, when I say that the only case I should not have at once promptly rejected as utterly unfitted for serum treatment from among the ten presented by Dr. Waxham, is No. 8. Of Case No. 1 I can not speak positively, owing to the meager report of physical signs, temperature, etc., given.

I wish here to point out that no clinical records are of any value which do not describe in detail the physical signs and conditions found. I was always taught, and by no less an authority than Sir William Broadbent, in recording clinical cases to give the details of the signs as found, leaving the deduction as to their significance to be made by the reader. Dr. Waxham has reversed this practice, giving only his deductions, and leaving the physical signs, etc., to be inferred. Every man has, of course, a right to his own method; but I must own that

to me the former seems far the more scientific, and when the subject is of a controversial nature, the more satisfactory.

In concluding, Dr. Waxham says: "It is possible that in incipient cases the A.P. serum may overcome the disease." As that proposition was clearly laid before Dr. Waxham at the outset as the extent of the claim, I fail to see why he should have tried to prove that it could not do what was never claimed that it could. He proceeds: "If it can be proven to be effective in early cases, thus preventing the necessity of a change of climate, it will indeed be a blessing to mankind." To this we can all agree; I will go further and add that without disparaging climatic, hygienic, nutritional and other modes of treatment, all of which can render valuable aid *where available*, we may reasonably propose for investigation the question whether serum treatment is not quicker, more certain, and more permanent in its results, even though it be conceded that such results are at present attained with more or less frequency by the methods above referred to.

What results may later be gained in cases with disintegrating or mixed infective processes (viz., all third stage and *late* second stage cases) by improvements in the serum, or by its alternate administration with anti-streptococcus serum, remains to be shown. But at present we reaffirm as rules for the selection of cases for treatment with the antiphthitic serum T. R. (Fisch):

1. It is *not* recommended to be used with any anticipation of good results in *any* third stage cases.

2. It is *not* recommended in any *late* second stage cases, i.e., with breaking down of tissue, especially if there be "mixed infection."

3. It is recommended in the so-called "pretubercular" stage, in the first stage, and in the early second stage prior to disintegration; and in these alone.

4. Finally, its advantages if it be proved to possess any, over climatic, hygienic, nutritional and other methods, will be found to lie in the attainment of results more quickly, more certainly, more permanently, and without the necessity of measures which in a very large proportion of phthical cases are unattainable.

If Dr. Waxham's paper helps to fix these points in the minds of prospective users of the serum, it will not have been published in vain; for it shows conspicuously "what *not* to do," which is oftentimes far more instructive than the converse.

Yours respectfully,

KENNETH W. MILLICAN, M.D., B.A., M.R.C.S.

Oxytuberculin.

SANTA CLARA, CAL., March 15, 1898.

To the Editor:—In the JOURNAL of March 12, 1898 (p. 621), Dr. J. O. Hirschfelder writes of "Oxytuberculin." In his article he states that "it was and is my desire that the doctrine of the curative effect of oxidized toxins should be most skeptically investigated, etc." That is just what I have been doing. The more I investigate the more skeptic I become, especially as regards "oxytuberculin." As to the Doctor not having "entered upon the field of animal experimentation, but limiting my work entirely to the clinical and bacteriologic sphere, etc.," I beg leave to call Dr. Hirschfelder's attention to plate 1, page 268 of the "Transactions of the Medical Society of the State of California" for 1897. This plate shows a dog upon whom the Doctor claimed to have experimented. The same plate, or one purporting to be the same, appeared on the first page of the *Daily Examiner* of San Francisco, Oct. 25, 1897.

Dr. Hirschfelder labors under a grave misapprehension as to my place of abode. Instead of a small village I live in an incorporated town of 3300 inhabitants. The town and surrounding country afford an excellent field for general practice. Again, I must beg to correct the erroneous statement that "he

has had some unpleasantness with a medical gentleman who is using oxytuberculin with most excellent success in Santa Clara." I have never an unpleasantness with a medical gentleman in my life. "Oxytuberculin" is being used "with most excellent success" financially, we presume. However, I challenge Dr. Hirschfelder or anyone else to produce a resident of the town of Santa Clara who has been positively cured of tuberculosis by "oxytuberculin." I want the diagnosis and cure above the suspicion of a doubt. There have been a number of cases here in which the disease terminated by death. I understood that "oxytuberculin" had been tried in these cases.

In one case which I have seen, and in which it is averred Dr. Hirschfelder examined the sputum a number of times before finding the tubercle bacilli, and then but a "few," there is a grave doubt in the minds of several reputable practitioners as to whether or not there is or ever was tuberculosis. There is evidence of an old pleurisy, a heart lesion and an aneurysm in the vicinity of the left common carotid artery. There is no hectic, expectoration or other important symptom which proves the existence of tuberculosis. Oxytuberculin was tried for a time with the result that the patient lost many pounds of flesh according to her own statement. After a cessation from the use of "oxytuberculin" she regained some flesh. Treatment directed toward the amelioration of the symptoms due to the aneurysm has made the patient much more comfortable than she had been in weeks.

As to the county hospital cases, I must say that I do not think that a full-fledged case of tuberculosis could subsist on thirteen cents a day very long. I think the diet rather than the oxytuberculin cut short those cases. The marvelous results which seem to have been claimed, have in one instance at least occurred in a patient said not to have been "expected to live a week;" I would ask the Doctor if this was an "early stage case."

I wish to call attention to the fact that the case or cases about which I wrote were in my own town and not under Dr. Hirschfelder's immediate care. I do know something about these cases. More than that, I have read the Doctor's reports of cases, and I must say that I do not think very many medical men are likely to know much about his cases from his reports, as they seem to be made up mostly of assertion and very little data of positive value.

I agree with the learned Doctor that "there should be no mud-throwing in the temple of science." However, in the pseudo-temple of science in which he would seemingly enshrine himself and "oxytuberculin," he must be responsible for what takes place. He has invited criticism and "skeptical investigation" and must not be dissatisfied or angry if such criticism comes from "a small village some fifty miles from here," or from a fair-sized municipality like Paris, for instance, some thousands of miles from here. I would beg leave to observe that the country practitioner is quite as apt to be skeptic and think for himself as is the metropolitan practitioner. In fact, the "country doctor" does not seem quite so much given to fads as his more or less fortunate city brother. Yours respectfully,

E. H. SMITH, M.D.

State Board Examinations.

FRANKLIN, KY., Feb. 22, 1898.

To the Editor:—Will you be kind enough to publish the names of all the States that require all graduates to stand an examination before the State board before they can practice?

Yours truly, W. A. GUTHRIE, M.D.

ANSWER.—Alabama, Arkansas, Florida, Maryland, Minnesota, Mississippi, New Jersey, New York, North Carolina, North Dakota, Pennsylvania, South Dakota, Texas, Utah, Virginia and Washington. *Vide JOURNAL*, Vol. 22, p. 351.

Let us defeat the Antivivisection Bill!

NEW INSTRUMENTS.

A NEW RECTAL SPECULUM.

BY THOMAS CHARLES MARTIN, M.D.
CLEVELAND, OHIO.

The instrument which is the subject of the following description was briefly described in the July (1896) number of the *Cleveland Medical Gazette*. It is now being quite extensively and, I regret to say, defectively manufactured. The italicized paragraph points to the defective features of many of the

Figure 1.

specula to be found at the shops. If this feature is not made to operate precisely as designed the instrument can not be manipulated with one hand unaided.

Figure 2.

This two bladed speculum is designed especially for use on the rectum. The form and dimensions of the blades have been planned with a particular consideration for the dimensions and form of the parts upon which they are to be used. The blades proper are two inches (5 cm.) in length, they are very shallow and their edges are given a pronounced inward turn; their acorn-like initial extremity contributes to the instrument's

facility for introduction, while at the same time especially qualifies it to be self-retaining. The inturned edges of the blades permit of easy rotation when in the bowel. The shallowness of the blades provides for the greatest possible exposure of the walls of the rectum when the blades are separated. The length of the blades has been determined by a consideration for the depth of the neck or lower contracted fixed part of the rectum. The blades are set at the ends of long outreaching and descending arms, a feature which gives much satisfaction when the instrument is in use. The length and curves of

Figure 3.

these arms afford four positive advantages: lying close along the surface of the nates, as they do, these parts are held aside; the blades are buried in the anus, no part of the blades or arms

Figure 4.

projecting above the surface to obstruct the field of vision and operation. These out-stretched arms permit approach to the exposed proximal wall of the rectum as well as to the distal; the great distance at which the blades are set from the joint provides for the simultaneous exposure of almost as great a surface of proximal wall as of the distal.

The easily working collar-button joint is a feature which

commends itself to those who appreciate the value of an aseptic instrument.

I feel sure that the quick lever-screw lock in the handle will also find favor. The perfectly constructed instrument will be locked when the lever is at one or the other of the two positions shown in Figs. 2 and 3. By such a provision the speculum may be locked and unlocked, opened and closed with one unaided hand. (Instruments defective in this particular may be corrected by filing a bit off the screw end.)

Designedly the speculum lacks a spring. My experience convinces me of the disadvantage of a spring between the handles of instruments designed to be used about the anus. The blades of that instrument which is provided with a spring are often rushed together with such force as to grasp and damage the mucous membrane. The sphincters and provide the only spring this speculum requires—the anus will not pinch itself. The speculum, which is springless, is not capable of any movement independent of the exercise of the operator's will, while the converse is true of the spring speculum.

The handles of this instrument are of such length that the pressure of the surgeon's grip is at the same distance from the fulcrum as are the blades; thus, in his sense of touch he may have at one and the same time an intelligent appreciation of the force he applies and of the resistance supplied by the sphincters.

With this speculum introduced to the rectum and rotated 45 degrees the surgeon may, aided by a proctoscopic mirror and proper posture of the patient, survey at a glance the whole of the interior of the rectum and a part of the sigmoid flexure.

The use of bivalvular, trivalvular, fenestrated tubular, or of specula of forms other than that of the complete cylinder provoke pain, therefore the above described rectal speculum is designed to be used only on the anesthetized subject.

1077 Prospect Street.

ASSOCIATION NEWS.

Section on Obstetrics and Diseases of Women.—All the members of the Section on Obstetrics and Diseases of Women of the AMERICAN MEDICAL ASSOCIATION who intend to participate in the Section dinner at the meeting of the Association in Denver, will please signify their intention by writing to Dr. E. C. Rivers, Chairman of the Section Dinners, Denver, Colo.

Section on State Medicine.—Members desiring to read papers in the Section on State Medicine are requested to send the title of their paper as early as possible to Dr. Arthur R. Reynolds, Room 2, City Hall, Secretary of the Section. Following is a list of papers already promised:

Maritime and Interstate Quarantine, by G. B. Thornton, President of Board of Health of Memphis, Tenn.

Isolation in a Great City, How Best Accomplished, by Samuel P. Duffield, Health Officer of Detroit, Mich.

The Relation of the Courts to Administration of Sanitary Laws, by William P. Munn, Health Commissioner, Denver.

Maritime Quarantine, by A. H. Doty, Quarantine Officer, Port of New York.

The Difference in Sanitary Quality Between Water and Ice from the Same Source, by Adolph Gehrmann, Superintendent City Laboratory, Chicago.

The Control of Diphtheria, by William K. Jaques, Chicago.

Concerning the Importance of Bacteriology in Preventive Medicine, by Franklin Staples, Winona, Minn.

Recent Investigation of the Action of Alcohol on all Growth, by I. D. Crothers, Hartford, Conn.

The Necessity for Mountain Sanitariums for the Treatment of Poor Consumptives, by J. H. Kellogg, Battle Creek, Mich.

Cold and Respiratory Diseases, by Charles H. Shepard, Brooklyn, N. Y.

The Treatment of Syphilis by the General Practitioner, by Harvey P. Jack, Canestoe, N. Y.

The Great Need of Central Resting and Recreation Places in the Large American Cities, by Thomas H. Manley, New York City.

Brain Surgery from Railway Injuries, by Clinton P. Herrick, Troy, N. Y.

Thalassic Submersion a Means of Disposal of the Dead, by Daniel Lichty, Rockford, Ill.

The Supervision and Licensing of Certain Industries Necessary by Their Bearing upon Public Health, by Ernest Wende, Buffalo, N. Y.

The following have promised papers: Benjamin Lee, Philadelphia; H. N. Avery, Minneapolis, Minn.; Lewis D. Mason, Brooklyn, N. Y.; Thomas F. Harrington, Lowell, Mass.

SOCIETY NEWS.

Kentucky Midland.—The Kentucky Midland Medical Association will hold its ninth quarterly meeting in Georgetown, Ky., April 14, 1898. Dr. F. B. Powers of Lawrenceburg is secretary.

Mississippi State Medical Association.—The thirty-first annual meeting of the Mississippi State Medical Association will convene in Jackson, Wednesday, April 20, 1898. Titles of papers should be sent, by April 1, to J. R. Tackett, secretary, Biloxi, Miss.

West Virginia State Medical Society.—The thirty-first annual meeting of the medical society of the State of West Virginia will be held in Martineburg, May 18, 19 and 20. Those wishing to read papers will send title to the secretary, G. A. Aeschman, M.D., Wheeling, W. Va., before May 1.

The Tri-State Medical Society of Iowa, Illinois and Missouri will meet at Dubuque, Iowa, April 5 and 6. The following have promised papers: R. N. Cresap, Bonaparte, Iowa; Albert H. Cordier, Kansas City; George Kessel, Creco, Iowa; Albert Green, Rockford, Ill.; Wm. E. Whitney, Eldora, Iowa; W. W. Peck, Darlington, Wis.; D. C. Brockman, Ottumwa, Iowa; James Moores Ball, St. Louis; F. A. Dunsmoor, Minneapolis; Byron Robinson, Chicago; John W. Kime, Des Moines; C. E. Ruth, Keokuk; A. C. Bernays, St. Louis; R. P. Berry, Clermont, Iowa; Gershom H. Hill, Independence; W. P. Hartford, Cassville, Wis.; T. J. Maxwell, Keokuk; Emory Lanphear, St. Louis; J. Scott Stevens, Cedar Falls; James H. Etheridge, Chicago; Francis Reder, St. Louis; C. C. Gratiot, Shullsburg, Wis.; Paul Paquin, St. Louis; G. H. Fuller, Delhi, Iowa; W. H. Byford, Chicago; G. Frank Lydston, Chicago; D. S. Fairchild, Clinton, Iowa; Thomas H. Manley, New York; Franklin H. Martin, Chicago; F. B. Dorey, Keokuk; J. R. Brady, Lamont, Iowa; E. O. Cisson, Keokuk; J. H. Craig, Volga City, Iowa; J. DeWitt Graham, Springfield, Iowa; L. J. Bowman, Greeley, Iowa; H. C. Temple, Waucoma, Iowa; Jacob Geiger, St. Joseph; William F. Waugh, Chicago; C. R. Pickering, Muscoda, Wis.; Thomas Bassett Keyes, Chicago; L. L. Renshaw, Monona, Iowa; J. J. Lindsay, Manchester, Iowa; W. B. Graham, Waterloo, Iowa; H. C. Markham, Independence; Charles H. Flinn, Postville, Iowa; N. J. A. Mueller, Dyersville, Iowa; J. J. Brownson, Dubuque and J. W. Osborn, Dyersville, Iowa.

Missouri State Medical Society.—The Medical Association of Missouri will meet at Excelsior Springs, May 24, 25 and 26, 1898, instead of the previous week as heretofore announced, the change being necessary to secure proper accommodations. The Committee on Scientific Communications (Drs. Emory Lanphear of St. Louis, C. H. Wallace of St. Joseph and Joseph Sharp of Kansas City) announces the following papers which are given and will be read in the order of their reception:

President's Address, Prof. Jacob Geiger, St. Joseph; "Pelvic Abscess," Prof. O. Beverly Campbell, St. Joseph; "Diagnosis in Infantile Diseases," O. P. Kernodle, Sedalia; "Delays in Surgery," W. B. Sisson, Kahoka; "Value of the Use of Diphtheritic Antitoxin in the Treatment of Pseudo-Membranous Croup," L. I. Matthews, Joplin; "Hypnotic Criminality," Joseph Taintor, Warrenton; "Enuresis of Childhood as It Frequently Extends in Its Results to and even Later than Puberty," Prof. J. M. Richmond, St. Joseph; "Report of a

Case of Cholecystotomy," Francis Reder, St. Louis; "Progress Made in the Treatment of Conditions Resulting from Microbic Infection," J. T. Marsh, Liberty; "Some Remarks on a Recent Epidemic of Typhoid Fever," H. H. Vinke, St. Charles; "Venesection in the Treatment of Disease," P. S. Fulkerson, Lexington; "Broncho-pneumonia," J. D. Brummall, Salisbury; "Nasopharyngeal Catarrh and its Treatment by the General Practitioner," S. S. Davis, Fulton; "State Medicine," Prof. J. M. Allen, Liberty; "Three Cases of Hysterical Vomiting," Prof. Jerome K. Bauduy, St. Louis; "Osteomyelitis," Prof. T. E. Potter, St. Joseph; "Occlusion of the Posterior Nares (bony), two Cases," J. Rule Fritts, Mexico; "Personal Experience in the Treatment of Uterine Fibroids," Prof. Walter B. Dorsett, St. Louis; "A Case of Extra-uterine Pregnancy Operated upon at the Eighth Month; Recovery," Prof. H. C. Dalton, St. Louis; Does Missouri Need a Home for Epileptics? Geo. R. Highsmith, Carrollton; "Quinin Bilindness; the Amaurotic Form of Tabes; Hydrophthalmos; Report of Cases," Prof. James Moores Ball, St. Louis; "The Way to Determine the Qualifications of Matriculates in our Medical Schools," W. Francis Mitchell, Lancaster; "A Rapid Treatment of Chancroid and Syphilitic Ulcerative Lesions," A. H. Ohmann-Dumesnil, St. Louis; "Physiologic and Pathologic Intemperance," Edward E. Parrish, Memphis; "Spina Bifida and its Treatment, with Report of Cases," Prof. T. F. Prewitt, St. Louis; "Some Phases of Intestinal Obstruction," Prof. A. H. Cordier, Kansas City; Report of Committee on Progress in Obstetrics, Prof. B. M. Hypes, chairman, St. Louis; Report of Committee on Progress in Gynecology, Geo. F. Hulbert, chairman, St. Louis; "The Progress of Phthisic Processes in the Lungs by Way of Bronchi," Prof. Wm. Ophule, Columbia; Report of Committee on Progress in Pediatrics, I. N. Love, chairman, St. Louis; Report of Committee on Progress in Surgery, Prof. Andrew L. Fulton, chairman, Kansas City; "Asexualization as a Preventive of Pauperism and Crime," R. S. Kelso, Joplin; "The Treatment of Chronic Hypertrophic Tonsillitis in the Light of Modern Theories of Infection Through the Tonsil," Prof. Hanau W. Loeb, St. Louis; "Report of Two Cases of Intracranial Aneurysm," Prof. J. D. Griffith, Kansas City; "Report of a Case of Castration for Enlarged Prostate, Followed One Year Later by Prostatectomy; with Presentation of Patient," Prof. C. M. Nicholson, St. Louis; Title unannounced, J. Block, Kansas City; "Fat Embolism, with a Report of a Case," T. B. Ellis, Bethany; "Stricture of the Esophagus," Paul Paquin, St. Louis; "When to do Colpohysterectomy, and Methods," Prof. Milo Buel Ward, Kansas City; "Surgical Anatomy of the Ankle Joint," Prof. Herman E. Pearse, Kansas City; "The Effects of Osteopathy upon the Patient and upon the Business of Reputable Physicians," Whitley G. Hendrix, New London; "How to Give Prompt and Permanent Relief in Prostatic Obstruction," Geo. Wiley Broome, St. Louis; "A Plea for Early Operation in Cholelithiasis," Prof. A. H. Meisenbach, St. Louis; "Facial Erysipelas; Its Treatment," Z. T. Martin, Lathrop; "Treatment of Hemorrhoids by the Clamp and Caustic Method," Prof. S. G. Gant, Kansas City; Subject unannounced, N. M. Baskett, Moberly; "The Application of Proctargol in Ophthalmic Surgery," Prof. B. E. Fryer, Kansas City; "Typhoid Fever," Robert E. Sevier, Liberty; "Traumatic Injuries of the Urethra," J. W. Holliday, Tarkio; "Electrotherapeutics," Prof. Brummell Jones, Kansas City; "Pneumonia," Tinsley Brown, Hamilton; "Injuries Produced by Bicycle Saddles and their Rational Remedy," John L. Short, Rolla; "Can Cancer of the Uterus be Cured?" Emory Lanphear, St. Louis.

NECROLOGY.

Dr. W. S. O'NEAL, M.D., of Lancaster, Ky., died at that place on March 15. He had been a sufferer from bronchial asthma for a number of years, and his last attack complicated by broncho-pneumonia was the cause of death. He was born at Verona, Boone County, Ky., 61 years ago, on October 3. He was graduated from the Ohio Medical College in 1861 and located at Verona, where he practiced for twenty-one years. Thirteen years ago he moved to Lancaster, Ky., where his only child had married, and soon had a large practice. He was a member of the State Medical Society for more than thirty years, and was much loved in the community in which he lived. He was recently appointed a member of the State Board of Health by the governor, which place he resigned shortly before his death.

JOHN T. CONKLING, M.D., College of Physicians and Sur-

geons, N. Y., 1855, died after about a year's illness at his home in Brooklyn, N. Y., aged 73 years. He was connected with the Brooklyn Board of Health as sanitary superintendent in 1866 and 1867. From 1874 to 1877 he was a health commissioner and introduced the ambulance system in Brooklyn. He was also for six years connected with the board of education, and despite his quiet unostentatious manner, was regarded as a public-spirited citizen.

E. A. PRAEGER, M.D., Los Angeles, Cal., March 6, aged 43 years. The Doctor was professor of gynecology, Los Angeles Polyclinic, Fellow of American Obstetricians and Gynecologists, Fellow of the Obstetrical Society of London, member of the British and Canadian Medical Associations, and Southern California Medical Society.

WM. P. MORRISSEY, M.D., New York University, 1869, for more than ten years a police surgeon in Brooklyn, died in his 52d year at his home in Greenpoint, N. Y., March 13. He was a Canadian by birth. A widow, three daughters and one son are his survivors.

P. D. BAKER, M.D., Franklinton, Pa., March 8.—F. P. Bell, M.D., Naples, N. Y., March 12, aged 39 years.—C. S. Boarman, M.D., Boonville, Mo., March 15, aged 72 years.—James S. Fulk, M.D., Baltimore, March 13, aged 69 years.

—W. C. Hobbs, M.D., New London, Iowa, March 2, aged 84 years.—L. M. Squire, M.D., Poynette, Wis., March 7.—J. J. Towle, M.D., Jamestown, N. Y., March 12, aged 61 years.—Alward M. White, M.D., El Paso, Texas, March 10.

DEATHS ABROAD.—J. C. Busch, M.D., Germany, prominent in legislative, professional and editorial activity.—W. Moldenhauer, professor of otology at Leipzig.—G. Kalischer, M.D., Berlin.—Anna Jelenewa, M.D., superintendent of foundling hospital at Nishni Nowgorod. Committed suicide on account of death of infant from defective hot water bottle.—M. H. Saenger, professor of obstetrics at Groningen.—Prof. Rudolf Leuckart, the distinguished entomologist and parasitologist of the University of Leipzig, born at Helmstedt in 1823. In 1847 he became Privat-Dozent at Göttingen, and in 1855 he was appointed professor of zoology in the University of Giessen. In 1870 he accepted a call to the corresponding chair at Leipzig, which he occupied till his death. Besides his great work "Die Parasiten des Menschen," which appeared in 1863, he contributed largely to the literature of his special department. As a teacher he was regarded throughout the scientific world as the greatest authority on the subject which he professed.—Prof. Waldemar von Schroeder, director of the Pharmacological Institute of Heidelberg.—Dr. Carl Nikolas, professor of hygiene in Lausanne.—Dr. Otto von Essen, of St. Petersburg, a Russian dermatologist, aged 35 years.—Dr. Mesnet, member of the Académie de Médecine and author of several works on the nervous system and hypnotism, aged 77 years.—Dr. Ludwig Ruge, aged 81, the oldest practitioner in Berlin.—Prof. Leopold Auerbach of Breslau, a writer on neuropathology, aged 69 years.—Dr. Paul Hasse, formerly medical director of the Brunswick Lunatic Asylum at Königslutter, aged 68 years.

PUBLIC HEALTH.

A Congress for the Study of Tuberculosis will convene at Paris, July 27 to August 2, under the auspices of a permanent committee consisting of prominent physicians, professors and veterinarians. L. H. Petit, general secretary, Menton (Alpes Maritimes), France.

The Carrasquilla Leprosy Serum has been found ineffectual by the committee appointed to study its action by the Academy of Medicine at Bogota, at the request of the government. Twelve patients were carefully treated by Carrasquilla and scientifically observed by the committee during a period of nine

months, and they report "with positive grief," that the serum failed to modify the symptoms or the course of the disease in any case (*Revista Méd. de Bogota*, December, 1897, just received). Carrasquilla's first announcement was made after only two months' experience with the serum.

Hospital Ships for Cuba.—The *Archivos de la Policlinica* mentions that the distressing conditions accompanying the transportation of sick and wounded soldiers to the Peninsula in the usual passenger steamers, have forced the government to provide some large vessels fitted up for hospital purposes alone. The first of the "transatlantic hospitals" has arrived at Havana and will have eight physicians, a pharmacist and a military officer on board when it leaves.

Serum Treatment of Yellow Fever.—Sanarelli has sent out a limited number of samples of his finished serum to colleagues in Brazil, this country, etc., begging them to use it strictly in accordance with his directions, so that the tests may be uniform and all cases rigorously observed. He remarks that the "effect on man will probably be favorable, judging from its efficacy in saving animals destined to succumb almost without exception to experimental yellow fever."

State Board of Health of Pennsylvania.—In *Public Health* (January) Dr. Benjamin Lee outlines the parsimonious treatment that befell his State Board during the year just closed. It seems that early in that year there occurred a most untimely accident and damage to sanitary, as well as more material interests, in the fact that the State capitol at Harrisburg took fire and was entirely destroyed, with most of its contents. This disaster not only deprived the board of its place of meeting at the capitol of the State, but it caused a loss of about \$544 in furniture, books and stationery. Many of the books it will be impossible to replace. The board should make earnest effort to induce the commission for the rebuilding of the capitol to provide for its permanent use a commodious, well-lighted, conveniently arranged suite of rooms, consisting at least of an anteroom, a room for the meetings of the board and room for that sadly neglected but most essential department of the work of the commonwealth, the Bureau of Vital Statistics. The last-mentioned room should contain fireproof cases for protecting the returns, which will soon become quite voluminous and will be of great value. It is recommended that a resolution to this effect be adopted at the current meeting. Indirectly, however, the burning of the capitol worked much more serious detriment to the interests of the board than the destruction of its office and property. Entailing a very considerable immediate outlay in providing a temporary place of meeting for the legislature, then in session, and a far greater prospective expenditure in rebuilding the ruined edifice, this disaster created an uneasiness in regard to the financial condition of the State government and inspired the members of the legislature with a zeal for indiscriminate retrenchment as unfortunate in its results in some directions as it was wise and commendable in others. So far from being met in a spirit of enlightened liberality by the members of that body, the Committee on Sanitary Legislation of the Board was obliged to content itself with acting on the defensive. Only by unremitting efforts did it succeed in obtaining the same meagre appropriation which had been doled out to it in the past, in preventing the repeal of certain acts of much importance to the sanitary welfare of the people and in preventing the enactment of others which were fraught with danger to the State. Was it necessity then that caused Dr. Lee, of all the State health officers, to endorse the Caffery bill?

Sanitation and Utilization of the By-Products of Dairies.—The Food Fair, which was held during the month of October in Boston, contained in its Agricultural Department an exhibit of interesting character, which had for its object the demonstration of certain new processes for utilizing the by-products in

dairies; namely, the skimmed milk, the buttermilk, and the whey. The exhibit brought out the merits of certain processes shown that have been devised by Alexander Bernstein of Berlin, at present in Boston. If we consider the enormous quantities of these by-products, probably more than twenty million quarts per day, the question of their better commercial utilization appears of the utmost importance as a matter of national economy. The milk is mixed with a small amount of wheat flour or other farinaceous material. The flour does not dissolve in milk, but can be maintained for a short time in a state of exceedingly fine division, approaching the state of the fat globules. If rennet is added, and certain precautions are taken, the milk will gradually curdle and retain the flour in an even and very finely distributed state in the curd. The further treatment is as usual; but the cheese, instead of being a hard, leathery substance, is soft and of loose texture. It seems that during the process of ripening the flour undergoes some changes, which impart a pleasant piquant taste to this kind of cheese. But the utility of this process has another application. This farinaceous curd, as it may be called, can be made so loose as to form a powder when dry; and it can then be mixed with more flour to form a dough suitable for baking purposes. After the casein has been removed, the whey remains. In another part of the exhibit is shown how this substance can be made into a pleasant beverage, of excellent taste and wholesome. To accomplish this the whey is treated in such a manner as to become perfectly clear and transparent by the removal of all undissolved matter. The popular idea that a beverage should be clear is not a mere fancy. In drinking, we wish to assist digestion and not introduce undissolved substances, which give additional work to the digestive organs. The finished whey to which the name of "wheyn" has been given, contains a considerable amount of lactic acid and a small amount of sugar, which is added to make it more palatable. As to its medicinal effects, it has long been known that whey is an excellent tonic in cases of general debility, in liver and in kidney diseases; but the fresh whey is out of reach for the city population, and the danger of possible infectious germs is another objection to its use. In "wheyn" we have a perfectly sterilized product, pleasant to the taste, which has all the essential features of whey as a beverage. It would be difficult to state whence the medical value of whey is derived. It is a remarkable fact, that animals fed exclusively with an artificial mixture of pure casein with sugar and the salts of the milk, all in proportion in which they are contained in milk, will invariably die in a short time, showing that there must be something in the constitution of milk which is not shown by analysis. "Wheyn" has been made sparkling to answer the purpose of a table beverage, and in this form it was shown in the exhibit above referred to.—*Journal of the Massachusetts Association of Boards of Health.*

BOOK NOTICES.

Lessons in Hypnotism and the Use of Suggestion, Based Upon the Neuron Motility Hypothesis. By LESLIE J. MEACHAM. Cincinnati, Ohio: The Bishop Publishing Co. 1898.

The author of this work, though a layman, has evidently studied considerable medical literature in the preparation of his book, which he says is "intended primarily for the use of physicians." Undoubtedly it may be of some interest to medical men, but its practical value is hardly likely to be as great as perhaps its author anticipates. Hypnotism has been before the medical profession in one form or another for over a century and has always had its advocates and the utilizers, but its actual practical benefits have never equaled expectations and the verdict of half a century ago is likely to be repeated now. This little volume, while intentionally scientific, has too much unsupported theory to be successfully so. Like

some really accomplished but not severely critical medical authorities who have injured their scientific reputations by an undue credulity in these matters, Mr. Meacham goes well beyond all possible scientific proof in his ideas of cures, telepathy, etc.

The book is interestingly written and strikingly illustrated.

The Nervous System and Its Diseases; A Practical Treatise on Neurology for Physicians and Students. By CHAS. K. MILLS, M.D., Professor of Mental Diseases and Medical Jurisprudence in the University of Pennsylvania, etc. Diseases of the brain and cranial nerves, with a general introduction on the study and treatment of nervous diseases; 459 illustrations, pp. 1056. Philadelphia: J. B. Lippincott Co., 1898.

Although the author intends, if circumstances permit, to follow this volume by another which shall include the remaining diseases of the nervous system, insanity and medical jurisprudence, the present volume is complete in itself with bibliographic and general index. The bibliography is very full, and the general index leaves nothing to be desired. The introductory portion of the work comprises a summary of the embryology, anatomy, physiology and chemistry of the nervous system, and a consideration of the general pathology, etiology and symptomatology of nervous diseases, with the methods of investigating them and the best measures applicable in their treatment. Close attention has been given to the subject of localization with regard to all portions of the encephalon. The nomenclature and terminology, advised by Prof. Burt J. Wilder of Cornell University have been in the main used throughout the book. Many of the illustrations are new and they are all clear and distinct. This work is very compact, concise and withal written easily. It is a pleasure to read the works of this writer and in this book his style is shown to its best advantage. The most difficult branches of this confessedly intricate subject are illumined by the pleasing style of the author. If one could have but a single book on diseases of the nervous system, he would not make a mistake in selecting this.

Fatty Ills and Their Masquerades. By EPHRAIM CUTTER, LL.D., M.D., and JOHN ASHBURTON CUTTER, B.Sc., M.D.; "being a contribution to clinical medicine for practitioners and students, to emphasize the inestimable value of the microscope in detecting the prestiges of amaurosis, angina pectoris, apoplexy, Bright's disease, cataract, dementia, fatty heart, gall-stones, glaucoma, hemophilia, locomotor ataxia, etc., and the like value of American means of treatment in these prestiges, and those advanced stages usually considered incurable."

That fat is the natural enemy of mankind every athlete knows, and if Dr. Cutter's book will better aid in getting rid of this persistent enemy, it will not have been written in vain. A number of cases are given in the peculiarly interesting style of the author, and they serve conclusively to illustrate the points the author makes. The book is entertaining, and even if one does not agree with the author's conclusions, he will at least be interested in the manner of stating his case. As an addition to American medical literature, it is unique and should find a place in the advanced medical library.

The Essentials of Experimental Physiology; for the Use of Students. By T. G. BRODIE, Lecturer on Physiology, St. Thomas' Hospital Medical School. Pp. 231. London, New York and Bombay: Longmans, Green & Co. 1898.

The aim of the author in writing this book has been to give a short account of those experiments which can be carried out by students during classes, together with a description of experiments suitable for class demonstrations. The illustrations are numerous and for the most part new. The contents of this volume comprise 22 chapters, namely, chapter 1, some physical instruments in constant use and in physiologic experiments; chapters 2 and 3, frog's muscle; chapters 4, 5, 6 and 7, experiments on muscular contraction, tetanus, fatigue of muscle, thickening, excitability, polarization of electrodes; chapter 8

experiments to determine the function of nerves; chapters 9, 10, 11, 12 and 13, experiments on frog's heart; chapter 14, demonstrations of the movement of the mammalian heart; chapter 15, experiments in electro-physiology; chapters 16 and 17, on the circulation of the blood, sphygmograph; chapter 18, the kidney, demonstration of oncometer experiments; chapter 19, demonstration of the nerves, regulation and respiration; chapter 20, demonstration of the secretion of saliva; chapter 21, reflex action excited upon the spinal cord of the frog; and chapter 22, experiments and physiology of the eye.

The work is well adapted for advanced students in the laboratory.

The Year-book of Treatment for 1898. A Critical review for Practitioners of Medicine and Surgery. Crown octavo; 488 pages. Cloth, \$1.50. Philadelphia and New York: Lea Brothers & Co. 1898.

This work is a trustworthy epitome of the year's progress in all branches of practical medicine. The aim of this book is to furnish a readable digest of the therapeutics of the year for the use of practitioners. Considering the compass into which it is compressed, it must be conceded that the editors have fairly succeeded in the work assigned them.

The list of contributors comprises Francis D. Boyd, Patrick Manson, Dudley W. Buxton, Malcolm Morris, Albert Carless, Edmond Owen, Alfred Cooper, Sydney Philips, George P. Field, Henry Power, Archibald E. Garrod, E. S. Reynolds, G. A. Gibson, Wm. Ross, M. Hanfield Jones, Gustav Schorstein, Reginald Harrison, Sinclair Thompson, Herbert P. Hawkins, Nestor Tirard, G. Ernest Hartman, W. J. Walsham, J. Ernest Lane, E. F. Willoughby, P. Luff and Dawson Williams.

The Therapeutics of Infancy and Childhood. By A. JACOB, M.D., Clinical Professor of Diseases of Children in the College of Physicians and Surgeons, New York, etc., etc. Second edition, pp. 629.

Although the author states that the revision of this book was begun immediately after its publication: that some of the chapters are rewritten, and a few new ones added, and that there is hardly one that has not been somewhat enlarged or otherwise changed, yet we have additional reason to reassert our favorable opinion of the book expressed in our issue, Vol. 26, 1896, p. 190. The fact of the early exhaustion of the first edition, which was published in 1896, carries with it sufficient evidence of its popularity with the profession.

Transactions of the Pathological Society of London in 1896.

These transactions have been a veritable mine of wealth not only to practitioners, but to hundreds of medical students in the throes of thesis writing. The latest, or forty-seventh, volume is now here fresh from the press of Smith, Elder & Co., and is for the year 1896. The excellence of the illustrations, so important to a work of this class, is great and constantly increasing. All the modern improvements in photography and allied pictorial presentation are liberally and wisely employed.

MISCELLANY.

Roentgen and Lenard Honored.—The Paris Académie des Sciences not only awarded the La Caze prize of 10,000 francs to Roentgen, but also bestowed the same amount upon Professor Lenard of Heidelberg, whose work on the cathode ray stimulated Roentgen to further research, and led to his great discovery.

Fate of Tetanus Toxin in the Alimentary Canal of Guinea Pigs.—Recent experimentation at Behring's Institute shows that the supremely toxic tetanus toxin is entirely harmless to the organism from the alimentary canal. It is not absorbed either from the stomach or the intestines, but passes unaltered through the entire canal and is thus eliminated *per anum*.—*Deu. Med. Woch.*, February 24.

Correction.—In the JOURNAL of March 12, in a note on Pittsburgh (page 630), mention is made of the specialists, and the name "Barham," is given. This should read "Hersman."

A Pitfall.—Mrs. Pokely: I understand from Mrs. Jokely that your doctor was guilty of conduct unbecoming a gentleman? Miss Meekly: Yes. Mrs. Pokely: Good gracious! When and what? Miss Meekly: O! constantly. My doctor's a lady.—*Philadelphia Record*.

"Death and Sudden Death."—This latest work by Dr. P. Brouardel has appeared in English dress, and is warmly commended by the critics as a veritable classic. And the author, who has for years been the official director of the Paris morgue, is *facile princeps* among the French medical jurists.

Postmortuary Parturition.—In German medical literature is found a term for which as far as we are aware, there is no English equivalent, viz., "Sarggebur," which literally translated means "coffin-birth," that is to say, that a pregnant woman dies and the body is placed in a coffin and then before or after burial, delivery takes place. Very few cases of this kind are on record.—*Medical News*.

Consolidation of the Spine After Reduction of Curvature.—Ducroquet has found by radiographs of patients taken several months after the hump had been forcibly reduced, that two-thirds to four-fifths of the gap has been filled by new osseous formation, a result surpassing expectation, and supplying a bony column of great solidity that ensures ample support to the spine.—*Nord. Med.*, v, 81.

Effect of the Roentgen Ray on Bacteria.—Perfect apparatus and technique have convinced Rieder that the Roentgen ray acts upon bacteria exactly the same as sunlight, only much more intensely, destroying them or at least checking their growth. His experience encourages further therapeutic application of the rays.—*Munch. Med. Woch.*, 1898, No. 4.

A Course of Lectures on Hydrotherapeutics has been provided in the annual appropriations for the University of Heidelberg, which thus takes the lead of all the German universities in this matter, although Vienna has been on the point of taking a similar step for some time. The Berlin University advocates including hydrotherapeutics in the course on general medicine, but protests against the creation of a special chair for any subordinate branch of medical training.

Vacancy to be Filled.—The chair of diseases of the eye, ear and throat, at the Medical College of Virginia, made vacant by the death of Professor Charles M. Shields, will be filled at the annual meeting of the board of visitors of the college, April 21. All applications, accompanied by credentials, should be forwarded to Christopher Tompkins, M.D., Dean, Richmond, Va.

Log Cabin Hospital for the Gold Hunters.—At Skaguay, Alaska, sickness and deaths by cerebro spinal meningitis have been the cause of much anxiety. So prevalent has the disease been that it has been spoken of as epidemic by some. A subscription for a hospital was promptly raised and a two-story log house was rented in the latter part of February; in that temporary shelter and in a cabin annex fourteen patients have been under treatment.

Maragliano's Aqueous Extract of Tuberculosis Bacilli has the same biologic and toxic properties as Koch's glycerin tuberculin. It is prepared by boiling the bacilli forty eight hours in distilled water. A precipitate is obtained by the addition of alcohol, and a desiccated extract by evaporation, which has the same properties as the original extract. The toxic action of each is completely neutralized by the antituberculosis serum. He considers water a better medium than glycerin, for several reasons.—*Gaz. d. Osp. e d. Clin.*, February 1.

Modifications in the Blood Produced by Cold.—Carrière announces

that recent investigations demonstrate that the corpuscles of the blood are very much modified by cold, in number, in shape, in histologic reaction, and in their functional activity. They relinquish a large part of their coloring matter and the serum becomes much more toxic than usual. This effect of cold on the blood resembles the effect produced by varnishing the skin and he is inclined to ascribe them to a similar mechanism.—*Bull. de l'Acad. de Méd.*, February 15.

An Appeal to the Men of Ohio; Let the Good Work Go On.—Send in your subscription promptly to the Rush Monument Fund. The object is a worthy one. There should be a representative statue of the American medical profession at the Nation's capital. Fifty cents each from the regular physicians of the State will make Ohio's contribution the welcome sum of over \$2500. Don't hesitate to send a small amount. Address at once the chairman of the committee, Dr. William E. Bruner, 514 New England Building, Cleveland.—*Cleveland Medical Journal*.

Practical Therapeutics.—Dr. Frank P. Foster's book in two volumes is reviewed with laudatory criticism in a prominent medical journal of London. The reviewer, among other good points made, says that "with one exception, Dr. Gordon Campbell of Montreal, all the contributors are Americans." Of course the reviewer knows where Montreal is located, but his pen slipped. He must have for the moment regarded America as a synonym for the United States, a territorial vastness that is not to be claimed by the most effusive of Yankees.

The Thyroid Gland in Chronic Icterus.—The necropsy of four cases of icterus from compression of the choledochus by neoplasms, showed a superactivity of the thyroid gland, while nothing of the kind is observed when the liver is not involved. Lindemann explains this superactivity by supposing that the bile and other substances insufficiently disintoxicated by the liver, passing into the circulation, start the other organs with similar disintoxicating functions, to extra exertion to supplement the hepatic insufficiency.—*Virchow's Archiv*, cxlix, 2.

Hermaphroditism a Variety of the Female Sex.—Virchow's experience has convinced him that on the whole, hermaphrodites belong to the female sex. He has never discovered a testicle in any hermaphrodite, although it is a difficult matter to decide exactly the nature of the seminal gland, upon which alone the actual question of the sex depends. There is only one authentic case on record (Obolenski's) in which both testes and ovaries were present.—*Klin. Therap. Woch.*, February 13.

Further Proof of Antitoxin in the Blood of Immunized Animals.—Serum from the blood of an eel is very toxic to certain animals, rabbits, dogs, etc., destroying the red corpuscles *in vivo*. Camus and Gley immunized rabbits against the action of the eel serum by inoculating them with small doses for a week or so, and found that a drop of serum from an immunized rabbit would protect the red corpuscles in a specimen of blood from a non-immunized animal, from the globulicidal action of the eel serum, thus furnishing a direct proof *in vitro* of the presence of an antitoxin in the blood of immunized animals.—*Presse Méd.*, February 12.

"The Archives of the Roentgen Ray."—Under this new name is now known the quarterly journal, of London origin, formerly styled the *Archives of Skiagraphy*. The publishers are the Rebman Company of the Strand, London. In England there exists a society having quite a considerable membership, medical men and others, called the Roentgen Society, which society has adopted this quarterly journal as the place of record for its proceedings. Single numbers are worth about \$1 to import, plus the postage, twelve cents. The editors are Dr. W. S. Hedly of the London Hospital, and Sidney Rowland, M.R.C.S., and they have the assistance of an editorial committee, fairly well stocked with medical men.

The Use of Wine at Table.—Last year a book of new verses or diet and allied subjects was put forth by Pope Leo XIII. Regarding the use of wine, the lines of the Pontiff show that he is no extremist, but pursues the golden mean. In the verses beginning, *Apponi in mensas jubeas purissima vina* his counsel is in effect, "Get only the best for your table; and free from care, soothe and refresh your heart with the grateful beverage, in the company of friends; but in all sobriety trust not overmuch to it as a restorative."

A Chemic Vaccine for Viper's Venom has been discovered by Phisalix, in tyrosin, found in certain plants, especially in the tubers of the dahlia and a mushroom. Two or three cubic centimeters of a hundredth solution will confer immunity to the venom upon a guinea pig after twenty-four hours, lasting frequently for twenty-five days. It has no antitoxic power injected at the same time as the venom, nor any effect as an antidote, but merely acts as a chemic vaccine, the first known example of the cellular juice of a plant possessing immunizing properties in regard to snake poison. The immunizing action of the cholesterin of bile and also of the vegetable cholesterin found in the carrot by Arnaud, has already been noted by Phisalix.—*Presse Méd.*, February 12.

The History of an Article.—We sometimes publish things twice. We recently printed an excellent article prepared by one of the JOURNAL staff, under the title of "*Hypnotism Before the Court*," in the Oct. 16, 1897, issue. The *Medico-Legal Journal* man of New York also thought it was a good article, and he printed it in his *Journal* in December, 1897, but forgot to credit it to this JOURNAL. One of our young men who looks into the exchanges with great care, and has special affection for the *Medico-Legal Journal*, recognized the article at once as being an excellent one, but did not recall that it was one of our own and it went out to the composing room and was published in our issue of March 19, 1898. As this JOURNAL always credits its esteemed contemporaries with whatever it takes from their columns, the article was duly credited to the *Medico-Legal Journal*, so that interesting publication received a valuable advertisement to which it was not entitled, although it has many other excellent features which entitle it to much credit as a rule.

Insanity on the Increase in Philadelphia.—The condition of the insane department of Philadelphia Hospital recently reported by the grand jury is interesting in many ways. According to the report the admissions to this department have increased 85 per cent. within the last ten years, while the proportion of the poor has decreased proportionately to the population and in point of actual numbers. So crowded has this department become that 1400 patients are accommodated in buildings intended for less than 900. In both the male and female departments, additional quarters are being constructed which will only permit of accommodations for 100 or 150 more. Beds have had to be placed in the aisles and passageways, in order to give sleeping facilities. To properly care for all the insane the Board of Charities and Corrections have asked that the districts of Germantown, Frankford and Roxborough be consolidated with Philadelphia.

A Novelist's Tribute to the Medical Profession.—In one of Farceon's Christmas stories, originally published in *All the Year Round*, that distinguished and admired writer takes occasion to make a most graceful reference to our profession, as follows: "It is my pleasure and duty to here cast in my tribute to this worthy and kind physician, whose life has been and is an honor to the calling of his choice. I can not refrain here from paying a tribute to this kind gentleman, whose life is an honor to the profession he adorns. But, indeed, in what ranks of professional labor can more unselfish kindness be found than in the ranks of those who minister to the sick? Surely there must be some beneficent influence in the work

they do that humanizes and softens the heart, that makes it respond willingly and cheerfully to the appeals of those who suffer? Numberless are the instances that can be adduced of the wonderful goodness of doctors, renowned and eminent, who sacrifice their time without expectation or desire of return for the inestimable services they render. I have no hesitation in saying that, of all arts, it is the most ennobling and beautiful, and that its record of kind deeds is matchless and unapproachable. With all my heart I say, 'Heaven bless the doctors for the good they do, for the good they are enabled to do!'—*The Scalpel*.

Opinions as to Cause of Death.—The rule as generally stated is that a medical witness may give his opinion as to the cause of death. But the supreme court of Kansas makes the very important suggestion, in *Davis vs. Travelers' Insurance Company*, February, 1898, that the most, if not all, of the cases out of which this rule has been collected are those of homicide, in which an opinion by a medical witness as to the cause of death rarely, if ever, involves the principal question submitted to the jury, to wit, the guilt of the accused. In other words, the opinion he expresses in such cases is upon the cause of the death, and not as to who caused it. Consequently, the supreme court intimates, but does not decide, because the question was not properly presented, that a different rule might obtain in cases where the principal fact to be tried is the cause of death, as in many actions on policies of life insurance. Save in such rare and exceptional cases as admit of no other method of proof, the court says, it would seem that opinions, whether by experts or others, are not admissible upon the ultimate fact to be found. It may also be noticed in this connection that the supreme court rather hints that hypothetical questions may be extended to too great length and be burdened with too great prolixity of detail, though the question of length is one very largely in the discretion of the court trying the case. Hypothetical questions to an expert witness, it further insists, should be based upon the evidence, and should not assume the existence of matters material to the formation of a correct opinion, about which no testimony has been given.

Physician an Uninterested Third Party.—It is an elementary rule of law that a stranger to a simple contract, from whom no consideration moves, can not sue upon it. But there is an exception to this, which generally obtains in this country, that where a promise is made to one person, upon a sufficient consideration, for the benefit of another, the latter may sue the promisor for a breach of his promise. Yet notwithstanding that, it recognizes this, the supreme court of Arkansas holds, in *Thomas Manufacturing Company vs. Prather*, Jan. 29, 1898, that a physician is such a stranger to it that he can not sue on a contract made between an employer and employe by which the employer is to furnish the employe medical attendance in case of accidental injury. Moreover, while the fact that the employe had called in a certain physician to attend him was known to the company in whose service he had been injured, and it had through its officers, fully approved thereof, might, in a suit brought by such employe against the company to recover of it, under a contract of this kind, the sum which he had paid his physician, be sufficient to estop the company from denying that it had waived its right to furnish its own physician, provided the company knew that the physician in question was called in reliance upon its contract to furnish medical attendance, the supreme court holds that it could not avail the physician anything in an action brought by him against the company.

Three Supposed Cases of Hydrophobia.—Recently three alleged or suspicious cases of hydrophobia occurred in Philadelphia and were examined thoroughly by both pathologists and bacteriologists. The first case was that of a lad 16 years of age who was bitten by a dog in September, 1897, and who died in the

Presbyterian Hospital six weeks afterward. The attending physician stated that the lad's saliva was frothy at times, and that three days before death the temperature rose to 100 degrees, and the next day 101, being 103 degrees on the day of death. In the second case no definite history had been given, but it was regarded as being suspicious. The third case, an adult male, was bitten by a dog last December and died at the German Hospital in February. The symptoms were frothing at the mouth at sight of liquids, together with spasms and convulsions. The first two cases were thoroughly examined by Dr. A. C. Abbott in the following manner: Sections of the spinal cords were obtained and from these specimens four rabbits were inoculated, two rabbits being inoculated with the supposed virus from the spinal cord in each case. One rabbit died the following morning from the effects of the operation and another died on the twenty-first day from congestion of the brain. The other two rabbits lived and developed no symptoms of hydrophobia. Dr. Cattell, the coroner's physician, made a postmortem in the first case and found that death had resulted from congestion of the brain. In the second instance Dr. Morton, the coroner's physician, after a thorough postmortem stated that death had been due to uremia, and in the third case that death had resulted from the same cause.

The Bladder in Hernias. Fifty-eight cases are on record since 1889 in which the bladder was involved in the hernia, all but one adults. Males, forty-two inguinal and one femoral; females, five inguinal and ten femoral. In only three cases was the involvement of the bladder diagnosed beforehand from disturbances in urination. In thirteen it was discovered during the operation and injury to it thus avoided. On the other hand the bladder was injured in no less than forty cases, in some by cutting, in others by the ligature, etc. The injury was discovered at once in twenty-five cases; in the others not until during the recovery or at the necropsy. In only one case was there an actual intraperitoneal hernia of the tip of the bladder entirely covered with serosa. In the rest the hernia consisted only of a portion of the organ, partially or not at all invested with serosa, but always more or less firmly adherent to the medial side of the hernia sac. In all cases studied the presence of a fatty envelope was noted as characteristic, an actual lipoma in some cases. If it can be detached when adhered to the hernial sac, without injury, the operation can proceed as usual, but if the bladder is injured or if gangrenous, suturing with after-tamponing seems indicated, although in three cases the bladder was sutured, reduced and the hernial wound sutured at once, with perfect success. Eleven cases terminated fatally; four as a direct consequence of the injury to the bladder. Small urinary fistulae have not affected the final success of the operation. In some cases described in detail in *Deu. Ztsch. f. Chir.*, xlv, page 245, twice the bladder was taken for an accessory hernial sac and opened, when the flow of urine announced the error. Another case requiring resection of a gangrenous portion of the peritoneum in a strangulated femoral hernia, was followed by peritonitis. A hole the size of a pencil was found at the necropsy, in the rear wall of the bladder, due to the operation.

A New Form of Operation for the Cure of Inguinal Hernia.—Swift (*New York Med. Jour.*, Oct. 23, 1897, p. 553) recommends the following procedure in the radical treatment of inguinal hernia: An incision is made a little below the level of and about an inch external to the anterior superior iliac spine, extending downward to the pubic epine, parallel with and about half an inch to an inch above Poupart's ligament. This extends to the aponeurosis of the external oblique, which is well exposed. A Kocher's director, or the finger, is passed through the external ring and the canal slit up to the internal ring. As the operation proceeds, all the bleeding should be promptly stopped by dry gauze or ligature when necessary, so as to pre-

vent the staining of the tissues and resulting obscuration of the field of operation. The hernia, if still unreduced, should be returned with or without first opening the sac, as may be required. The sac is now isolated from the cord by blunt dissection. If it can not be readily found, the mass should be held up, the vas deferens found, and while guarding it from injury, a longitudinal incision is made into the mass. This procedure will be found to open up the sac. The finger is then introduced into the sac and well up into the internal ring and a catgut ligature applied around it as high as possible, the finger being withdrawn gradually as the assistant tightens the ligature. The sac should be excised below the ligature. While the cord is held out of the way, three or four (in extreme cases more) sutures should be passed through the transversalis fascia, the conjoined tendon (if necessary also through the rectus abdominalis), the muscular fibers of the transversalis and the internal oblique, and the aponeurosis of the external oblique, on the one side, and about three-eighths of an inch from their edges. The sutures are double-threaded and are passed from within outward. Both free ends of each suture are now passed through the deep parts of Poupart's ligament about half an inch apart, and tied. Care should be observed that the suture next to the cord does not interfere with its circulation. The next step in the procedure consists in overlapping the superficial edge of Poupart's ligament and the lower part of the cut aponeurosis of the external oblique, and sewing the former well up on the anterior surface of the latter muscle. The ligament should be drawn firmly up and the line of sutures not placed so near the edge as to soon tear through. In addition a couple of sutures should finally be placed back of the lost line, which should pass through the overlapping Poupart's ligament and take generous bites of the overlapped structures. The last sutures are placed about midway between the others and serve to hold the flap more securely. When the veins of the cord are enlarged their number may be reduced by Halsted's procedure, and when the cord is otherwise large, some of the redundant tissue may be peeled up. The canal is now obliterated and the cord lies beneath the skin. The suture material consists of catgut hardened in iodoform and alcohol, or in mercuric chlorid and alcohol. Drainage is not provided for, except in operations on large hernias, when a few strands of silkworm gut are inserted. Usually only a few strands of this material are placed under the skin and they are removed at the first dressing. Rest in bed for six weeks or the wearing of a truss for that length of time is further recommended.

The Alleged "Boycott" of the British Army Surgical Department.—

The London *Practitioner* points out that it is an error to say that the medical profession of that country has declared a boycott against the Army Surgical service, and that if any such act has been committed it can be found in the systematic slight and ignominies that have been put upon the medical corps by bureaucratic officials. When military rank shall have been accorded to the surgeon, says the *Practitioner* the government may expect to get something better than "the refuse of the profession" for the Army Surgical Department, but not before. The contumelious treatment of that department has been so prolonged and emphatic that the wonder is that the surgical *personnel* is as good as it is. The *Practitioner* says: "The complaint about the boycotting of the army by the doctors, which has been recently made in Parliament and in certain newspapers, are to the last degree disingenuous. The army, as represented by its combatant officers, seems to take a special pleasure in boycotting the doctors, and it is surely not to be wondered at that doctors who have any regard for their own dignity should not care to expose themselves to such treatment. As things are, the army for the most part gets the mere refuse of the profession, and it will never get anything else while the present system of official snubbing of medical officers on every

possible occasion, and of treating them as in a military sense 'camp followers,' and socially as unfit to come between the wind and the combatant's nobility, is allowed to continue. Till the army doctor is given military rank with its full privileges, and is recognized not merely *de jure*, but *de facto*, as an officer and a gentleman, and treated as such, it is the duty of the teachers in the medical schools and of every member of the profession who is in a position of influence, to recommend young medical men not to enter the Army Medical Department. Why one of the leading medical journals should be so vehement in denying that this is an 'Army medical boycott' is not clear. The name given to the process, however, matters nothing. Let us call it 'abstention' if that sounds better. The important thing is to get youngsters to 'abstain' from putting on the livery of degrading servitude into which the War Office has transformed the Queen's uniform as far as doctors are concerned."

Loss of Life by So-called "Hunting Accidents;" Legislation for Its Prevention.—A bill has been presented to the legislature of Maine to establish a penal clause against those men with guns who "accidentally" wound or kill their fellow-men in the woods. This measure has been prompted by the unfortunately large number of fatalities which have occurred during the past season and the fall of 1897. If it becomes a law it is believed that the measure will operate as a means of saving human life. It is claimed that the hunters who wound or kill persons are mostly novices, who become excited and blaze away at any moving object they may see. It is proposed to put up notices of the law at all points where sportsmen enter the woods, at the various camps, railway stations, etc. Three so-called "hunting accidents" occurred in Maine almost as soon, in 1897, as "the law was off" deer. These were fatalities, while the number wounded but not killed was much larger. In Vermont a similar unfortunate record was made. Such results can but be set down as due to gross carelessness, although beyond question the shootings were not intentional. The average inexperienced hunter is so anxious not to return to his fellows from his hunting trip empty-handed that it is easy to understand his overzeal, but these mistakes have occurred so frequently that they should have been, and should be made to be, an effective warning. The number of cases may have been lessened through these sad experiences below the number they might have attained to had not a very wide publicity been given to each.

North Carolina Medical Law Constitutional.—Sections 3122 and 3132 of the Code of North Carolina, as amended by Acts 1885, chapters 117 and 261, by Acts 1889, chapter 181, sections 4 and 5, and by Acts 1891, chapter 420, relating to the examination and certification of persons desiring to practice medicine in that State, the supreme court of North Carolina hold, does not offend the provisions of the State constitution, which forbid exclusive privileges and emoluments to any set of men and prohibit monopolies and perpetuities. Nor does it consider that there is any infringement on the constitution of the United States, which prohibits any State to deny any person the equal protection of the laws. Moreover, it does not agree with the contention that the statute is unconstitutional on the additional ground that it exempts from its requirements those physicians who were already practicing medicine and surgery in North Carolina on March 7, 1885. The supreme court says, Dec. 23, 1897, case of State vs. Call, that the first statute, making it indictable to practice medicine and surgery without an examination by the State Board of Medical Examiners, and a license therefrom was enacted at the session of 1885, and was made prospective, so as to apply only to those who should begin the practice of medicine and surgery thereafter. This, it declares, was not unreasonable. It was fair, it somewhat tartly continues, to assume that those already in the practice, many of whom had grown gray in the service of humanity and the alleviation of suffering, had already received that public approbation which was a sufficient guaranty of their competency, and should not be needlessly subjected to the humiliation of an examination by the side of beardless boys, who had not yet swung a scalpel, or prescribed a purgative, save under supervision; while those already in practice, who had proved incompetent, it might be assumed had been equally stamped with public disapproval at the cost to the public of much bitter

experience, an expensive and dangerous process of distinguishing the two classes, to save the public from which, in future, was the object of the new regulation requiring examination and license by a board of competent examiners.

Louisville.

STATE BOARD OF HEALTH.—There is a contention in the State Board of Health which bids fair to grow quite warm before long. The terms of Dr. J. M. Mathews, the present President and Dr. J. O. McReynolds, having expired, the Governor re-appointed Dr. Mathews, and in place of Dr. McReynolds appointed Dr. W. S. O'Neal of Lancaster. Dr. J. B. Kinnaird of Lancaster, an appointee of the Governor on the Board resigned his position in order to become a candidate for the Secretaryship to succeed Dr. J. N. McCormack of Bowling Green. The Secretary is elected each year by the Board and is not considered a member of the Board in the true sense of the word. In Dr. Kinnaird's place the Governor appointed Dr. Fulton. On account of the untiring zeal of the present Secretary, Dr. McCormack, in ridding the State of the quacks and in getting the bill preventing the practicing of osteopaths in the State, passed by the Legislature, Dr. McCormack has made a number of enemies, both in and out of the profession, and they are using every effort to make the race for the Secretaryship a heated one, bringing it down to a level with politics. It is understood that all of the appointees of the Governor at the present time are pledged to vote for Dr. Kinnaird for Secretary, with the exception of Dr. Mathews. A majority of the Board as now constituted are appointees of the present Governor and there is a possibility of the plan to defeat Dr. McCormack being successful.

JENNIE CASSEDAY INFIRMARY.—This institution, which since April, 1892, has been maintained by the "King's Daughters" of the city has just been sold to Dr. Lewis S. McMurtry, the purchase price being \$15,000. On the above date the institution was first started, Dr. McMurtry being elected surgeon in chief with the following staff: Consulting physicians, Wm. Bailey, Thomas H. Stucky; consulting surgeons, J. M. Mathews, Geo. W. Griffiths. Since that time the institution has done remarkably well, but the King's Daughters were unable to meet the maturing notes with the interest, consequently the sale above mentioned was consummated. It will be run as a private infirmary by Dr. McMurtry.

SMALLPOX.—The situation at Middlesboro continues grave, especially as complications have arisen in regard to authority, State or Federal. The Governor and President of the State Board of Health were notified that there were 70 cases of smallpox and 400 suspects in the city and not a cent to meet current expenses. The funds of the State Board are exhausted and to meet the emergency, the Governor sent an emergency message to both branches of the legislature, sitting its last day of the session, urging the necessity of an appropriation for the purpose of stamping out the disease, but none was passed. Realizing that the funds were not available from the State, and no possibility of the town or county raising the money, with the consent of the Governor the State Board wired Washington, asking for assistance. In response to this, Passed Assistant Surgeon Wartenbaker was dispatched to the scene at once. For two days there was a conflict of authority but this was amicably settled and the Federal and State authorities are now working in harmony. A stricter quarantine is being enforced, and the isolation and detention hospitals will be moved to the far outskirts of the town. More money is now available from private subscriptions. Drs. J. M. Mathews, Wm. Bailey and J. N. McCormack went to the scene of the epidemic last week to investigate the situation in person.—Two cases of smallpox are reported at Richmond, Ky.

LEGISLATION.—The Governor has signed the "osteopathy" bill which requires these quacks to comply with the law governing the practice of medicine in the State previously referred to in these columns. The bill governing the practice of dentistry was vetoed.

INDICTMENT.—The following physicians of Covington were indicted by the grand jury of Kenton County for failing to

comply with the State law requiring medical practitioners to register at the office of the county clerk: Robert Furnam, John E. Stevenson, Charles E. Ellis, B. F. Laird, R. H. Crisler, F. D. Crigler, A. W. Devoss, Wm. L. N. Armstrong. They will combine and test the constitutionality of the law in the court.

CHOLERA VACCINE COMPANY.—Articles of incorporation of a company by this name have just been filed at Frankfort, with the Secretary of State. The capital is \$10,000. Two of the incorporators are Dr. Frank Eisenman, State Veterinarian, and Dr. John E. Cashin, State Bacteriologist. The object of the corporation is to manufacture and sell a vaccine against cholera in animals.

Detroit.

AT THE REGULAR MEETING of the Detroit Medical and Library Association March 14, Dr. J. V. Becelaere read a paper on "Professional Secrecy," in which the author outlined the legal conception of the subject, confining his remarks to the definition of professional secrecy as given by the courts of the different States in the Union.

AT THE REGULAR MEETING of the Wayne County Medical Society March 17, Dr. E. V. Riker read a paper on "Non-penetrating Injuries of the Eye." Dr. R. W. Gillman followed with a paper on "Penetrating Injuries of the Eye and Foreign Bodies." The Doctor said that the fear of sympathetic ophthalmia has influenced surgeons to sacrifice seemingly slightly wounded eyes. The Doctor is not in favor of immediate enucleation of the eye in this class of cases, but insists on the necessity of keeping the patients under close observation for some time, when, by the extent of the inflammatory reaction, the best way of dealing with the case can be determined. He reported a remarkable recovery to normal vision of an eye that was apparently destroyed in October, 1892, by a chip of steel from a hammer, which pierced the right cornea at the temporal side of the sclerocorneal junction, making a rent in the iris and passing back into the vitreous. The Doctor made three attempts with different-sized tips of a Hirschberg magnet forty-eight hours after the accident to remove the steel, but without success. In the manipulations the vitreous had been pretty thoroughly stirred up without any after-disturbance whatever. The eye healed and at the present time, six and a half years after the injury, the vision of the injured eye is $20/30$. The patient was presented to the Society and examined by the members present. In the fundus of the affected eye, a few mm. to the outer side of the macular region, is a deep fissure involving the retina, choroid and sclera. In the central part of this, which shows as a white patch, a pointed, bluish-gray object projects anteriorly and downward into the vitreous. This object is undoubtedly the sliver of steel that was projected into the patient's eye at the time of the accident. The object has almost the exact appearance of a cysticercus. Dr. Don M. Campbell read a paper on the subject of "Mules' Operation," outlining the technique of the operation and discussing its merits and its superiority over enucleation. Dr. J. H. Sanderson discussed the subject of "Tinnitus Aurium."

HEALTH REPORT for the week ending March 19: Total births 83; males 41, females 42; total deaths 81; under 5 years 33.

Cincinnati.

THE MORTALITY REPORT for the week shows: Zymotic diseases, 11; phthisis, 19; other constitutional, 9; local, 76; developmental, 8; violence, 4; still-births, 13; total 127; annual rate per 1000, 16.30; under one year, 18; between one and five, 14; preceding week, 107; corresponding week, 1897, 138; 1896, 126; 1895, 133.

THE ORGANIZATION of the medical corps to look after the veterans in attendance at the coming annual encampment of the G. A. R. is announced as having been divided into eight sections as follows: Medical director, Dr. J. C. Culbertson; camp under medical inspector Byron Stanton; school buildings under medical inspector A. B. Ieham and deputy inspector A. B. Birchard; Grand Central and C. H. D. railway depots under deputy inspector M. E. Bloyer; Pennsylvania and Northern railway depots under deputy inspector J. M. Crawford; emergency corps under deputy inspector J. G. Hlyndman; ambulance corps under deputy inspector L. C. Carr. The entire corps is to be uniformed at their own expense and all services

rendered are to be gratuitous. The commissions are to be issued by the citizens' committee.

DR. CHARLES H. MYERS has been appointed district physician to succeed Dr. J. E. Stephan.

DR. E. GUSTAV ZINKE will deliver a lecture at the Odeon March 23, on Nansen's "Successful Expedition to the North Pole." The proceeds are to go to the German Deaconess' Home and Hospital.

Societies.

The following meetings are noted:

Illinois.—Chicago Medical Society, March 16 and 23; St. Clair County Medical Society, Belleville, March 11; Vermilion County Medical Society, Danville, March 8.

Missouri.—Lafayette County Medical Society, Higginsville, March 8; Medical Society of City Hospital Alumni, St. Louis, March 17.

New York.—Albany County Medical Society, Albany, March 16; Binghampton Academy of Medicine, March 15; Medical Society of Newburg Bay, Newburg, March 8; Onondaga Medical Society, Syracuse, March 15; Rensselaer County Medical Society, Troy, March 8.

Ohio.—Cleveland Medical Society, March 11; Lorain County Medical Society, Lorain, March 13.

Pennsylvania.—Delaware County Medical Society, Chester, March 10; Lebanon County Medical Society, Lebanon, March 8.

CHANGE OF ADDRESS.

Barber, W. M., from Scio, Ohio, to North Liberty, Pa.; Blackburn, R. S., from Keokuk, Iowa, to Breeds, Ill.

Clark, I. S., from Keokuk, Iowa, to Dexter, Mo.; Caspers, P., from 356 W. Division St., to 2107 Michigan Ave., Chicago, Ill.; Creswell, G. W., from 36 Spruce St., to 8 DeKalb St., Chicago, Ill.

Guerard, A. R., from 2143 7th Ave., to 2041 7th Ave., New York, N. Y.; Hefelbower, R. C., from 7th and Elm to Groten Building, Cincinnati, Ohio.

Murrell, T. E., from Tucson, Ariz. Ter., to 2224 E. 14th Ave., Denver, Colo.

Paine, H. M., from Atlanta, Ga., to Glens Falls, N. Y.; Peabody, C. H., from Toledo, Ohio, to Mulliken, Mich.

Risjord, J. N., from Keokuk, Iowa, to Horeb, Wis.

Sargent, A., from Frankfort to Hopkinsville, Ky.; Shortridge, W. R., from Keokuk, Iowa, to Hopkinton, Iowa; Straley, S. B., from Pasadena, Cal., to Huntsville, N. J.; Shollenberger, C. F., from 2309 Larimer St., to 2301 Larimer St., Denver, Colo.; Starr, J. M., from Chariton to Lacona, Iowa; Stringfield, C. P., from 300 31st St., to 138 Jackson Boul., Chicago, Ill.; Slagle, C. D., from Portsmouth, Ohio, to Box 114, Pomona, Cal.; Sullivan, T. J., from 4729 Ashland Ave., to 4709 Michigan Ave., Chicago, Ill.

Weaver, W. H., from 126 State to 92 State, Chicago, Ill.; Wagner, H. E., from Ashland and Milwaukee Aves., to 551 Armitage Ave., Chicago, Ill.; Warner, A. L., from Hospital to Penfield, Ill.

Yates, H. W., from 1411 Fort St., W., to St. Luke's Hospital, Detroit, Mich.

LETTERS RECEIVED.

THE PUBLIC SERVICES.

Army Changes. Official List of Changes in the Stations and duties of officers serving in the Medical Department, U. S. Army, from March 12 to 18, 1898.

Major Joseph B. Girard, Surgeon (Jefferson Bks., Mo.), is granted leave of absence for three months, to take effect on or about April 1, 1898.

Capt. Madison M. Brewer, Asst. Surgeon, is granted leave of absence for one month on surgeon's certificate of disability, to take effect upon the expiration of the ordinary leave of absence.

First Lieut. Thomas S. Bratton, Asst. Surgeon, the order assigning him to Ft. Leavenworth, Kan., is revoked, and he is relieved from duty at Ft. Niobrara, Neb., and ordered to Tybee Island, Ga., for duty.

Capt. Francis J. Ives, Asst. Surgeon, is relieved from duty at St. Francis Bks., Fla., and ordered to Ft. Wingate, N. M., to relieve Capt. Adrian S. Polhemus, Asst. Surgeon. Capt. Polhemus, upon being so relieved, is ordered to Ft. Columbus, N. Y.

Capt. William E. Purviance, Asst. Surgeon, is relieved from duty at Ft. Columbus, N. Y., and ordered to Ft. Morgan, Ala.

Capt. Allen M. Smith, Asst. Surgeon, will be relieved from duty at Ft. Reno, Oklahoma Terr., upon the arrival there of First Lieut. Henry A. Webber, Asst. Surgeon, and ordered to Ft. Hamilton, N. Y.

First Lieut. James S. Wilson, Asst. Surgeon, is relieved from duty at Ft. Clark, Texas, and ordered to Ft. Caswell, N. C.

Navy Changes. Changes in the Medical Corps of the U. S. Navy for the two weeks ending March 19, 1898.

Surgeon L. B. Baldwin, detached from the "Puritan" March 17, and ordered home with two months' leave.

Surgeon J. D. Gatewood, detached from duty at the naval museum of hygiene, Washington, D. C., March 15, and ordered to the "Puritan" March 17.

Asst. Surgeon C. D. Kindleberger, detached from the "Olympia" and ordered home with two months' leave.

Surgeon N. H. Drake, detached from duty with the "Minneapolis" and "Columbia" and ordered to the "Minneapolis" March 15.

Surgeon C. G. Herndon, ordered to the "Columbia" March 15.

Medical Inspector W. S. Dixon, detached from the "Brooklyn" and ordered at once to the hospital at Norfolk, Va., for treatment.

Medical Inspector P. Fitzsimons, detached from duty as a member of the board of inspection and survey, Washington, and ordered to the "Brooklyn."

Surgeon J. E. Gardner, ordered to the "Dolphin" March 21.

P. A. Surgeon T. W. Richards, detached from the New York navy yard and ordered to the "Machias" March 22.

P. A. Surgeon M. R. Pigott, detached from the "Machias" March 22, proceed home and wait orders.

THE FORM OF TYPHOID FEVER CALLED MOUNTAIN FEVER—WIDAL'S TEST.

AFEBRILE CASES.

BY CHAS. E. WOODRUFF, M.D., U. S. ARMY.

JACKSON BARRACKS, NEW ORLEANS, LA.

When the eastern part of the United States was being settled, it was discovered that peculiar fevers arose. It is now almost certain, that at first the fevers were invariably malarial, but as the lands became drained, the farms cultivated and the water supplies infected with typhoid bacilli imported by the settlers, malaria disappeared and typhoid fever took its place. The first is the disease of new lands, the latter the result of insanitary conditions brought about by the settlers themselves. In the stage of transition there were numerous cases of "low fevers" which could not be positively stated were malaria or typhoid and for a while it was thought that double infections or hybrid cases occurred, hence the former frequent use of the obsolete term typho-malaria. As for double infections we know that they are so extremely rare as to need no further consideration, and if a doubtful case does not respond to quinin and does not show the plasmodium of Laveran it is surely typhoid. As for a hybrid disease neither malaria nor typhoid, we can be equally positive and state that since the discovery of Laveran's organisms and the typhoid bacillus, no such case has ever been found. The old method of giving quinin in typhoid no doubt arose from thus curing the malarial cases which were believed to be typhoid.

Now, in the early history of the settlement of the elevated western parts of the country, a similar confusion occurred in relation to its fevers. In those parts of Montana in which the writer has lived it can be positively stated that there is no native malaria. Every case found is an importation; for instance, a soldier or civilian arrives from St. Louis and after a few months has chills, fevers and sweats, the plasmodium is found and the case is promptly cured by quinin. Such cases curable by quinin and in which the malarial organism is found, never arise in persons who have lived a long time in the West, that is, a time sufficiently long to exclude the possibility of the organism having remained latent in the liver and spleen. There is no data at hand to substantiate such a dogmatic statement, but it can be accepted as the writer's individual experience. Now, the rarity of malaria was not known at first and indeed is not now known, for that matter, for the writer has personally seen typical cases of typhoid fever, diagnosed and reported as malarial remittents, treated with small doses of quinin and when the case recovered in due time, it was held up as a triumph of the persistent use of small doses of quinin for three or four weeks. With modern methods such absurd mistakes are im-

possible. In early days no doubt malaria was imported as now, and no doubt that typhoid was also imported, but physicians had so many atypical cases of fever that a new name was coined for them, "mountain fever." Whenever a case went to the postmortem table, the lesions of typhoid fever were invariably found, so that a few physicians dropped the term at once. An effort was made to prove that mountain fever was typho-malaria, and if the proof was logical, then there is no such thing as mountain fever because there is no typho-malaria. It was supposed that the term mountain fever was obsolete, but recently a Montana physician has informed the writer that such a disease really exists, that severe cases of fever are undoubtedly typhoid but the milder cases are not. Now, a great deal of this confusion results from ignorance of the fact that when a new country is being settled the first cases of typhoid are rarely recognized, because of their atypical nature. Even in the older East many physicians still refuse to call a case typhoid unless the fever lasts three weeks or more and is severe. Then again it is quite safe to assume that the altitude or some other unknown causes, effect a decided change in the character and activity of the bacillus, causing cases somewhat different from those in the East. But the differences are not marked, for it will be found that every eastern city has just as great a proportion of atypical cases as appear in the West. Indeed the occurrence of typical typhoids is so rare that we are astonished to find one. It is so variable that at one time it was considered to be due to several causes, several varieties of bacilli. Every case in the West can be exactly duplicated in the East by men of large experience. Now, this rule of absence of rigid type was not known by the earlier western physicians, hence they only too readily appropriated the term mountain fever. There are a large number of residents of Montana who are so thoroughly imbued with the idea that it is the best climate in the world, that they will not listen to any such bosh as the prevalence of typhoid fever. Records show that typhoid fever has occurred now and then at Fort Custer for years, and one postmortem of a man who died after a few days sickness showed perforation. In spite of all these cases, an old resident of Fort Custer told the writer that he never heard of a case of typhoid fever in Montana. Some of this feeling of local pride possibly blinds a few of the physicians; for instance, a certain physician saw one of the writer's cases in which the roseola was perfect and the course of the disease left no doubt as to the diagnosis, yet he said it was only a "touch" of malaria and she would be "up" in a few days. She had been "down" more or less for three weeks and was "down" about ten days after his diagnosis was made, the quinin taken not having a particle of influence. In another case, the man was advised to go to bed at once, but concluded to consult a physician of Billings, who thought it was

mountain fever and advised him to return to the hospital. The patient thought he could cure himself with a "good drunk," but did not succeed, and when he did come into the hospital he was one of the worst cases we had.

Finally, the same series of events is now taking place in the West as it has already taken place in the older East, that is, the more concentrated the population becomes the quicker is the infection from patient to patient, and the more closely do the cases resemble the typhoid we were accustomed to call the classic type. Formerly, when the water courses were not markedly infected, it is reasonable to assume that considerable time may have elapsed after the bacilli were discharged from one patient before they were taken up by another, a time in which it is perfectly possible, even probable, that they took on new and less malignant characters. Just as soon as a western town or neighborhood becomes crowded and it is possible for the water-supply to become polluted, the cases are infected almost from one patient to the next, not giving time for the bacilli to lose virulence, but possibly increasing in virulence. As a consequence, the cases are so severe as to leave no doubt as to the diagnosis. Hence the term mountain fever is not heard nearly as often as formerly, and then only in the more remote, smaller towns, or in isolated places, where we can presume cases occur as they did twenty-five years ago.

During the past summer and fall, there occurred at Fort Custer, Montana, an epidemic of fever, which was undoubtedly typhoid and which could have been pronounced mountain fever by those who hold to such views, and the following analysis of the cases is made with the express purpose of helping to abolish the use of such an illogical term.

It is an old habit to conceal one's ignorance of the disease he is treating by giving it some neutral name such as "slow," "pernicious," "gastric," "bilious," "typho-malarial," "swamp," "Red River fever," "irritative," and so on indefinitely. In epidemics when it is desired to conceal the true state of affairs the same euphemism is used. Nowadays when the public is beginning to recognize that every case of infectious disease is apt to spread the poison broadcast, they are calling for definite diagnoses and the abolition of meaningless terms.

The danger of typhoid is extremely great as a moment's thought will show, because no means are taken to disinfect the stools, and dieting is considered superfluous. The water courses are becoming more and more infected and are spreading fatal typhoid throughout the whole West. There is already a frightful state of affairs in some localities. If rumor is to be believed a bad epidemic has occurred in Miles City from infection brought down by the rivers, for every town considers itself entitled to pour its sewage into its river, to be consumed by the next town below. In arid countries like Montana, where the only available water is in the streams, as wells and springs are not to be found, it certainly behooves the people to take measures to protect the streams. They are the very life of the country, for no one can live very far from them; unless care is taken they will be the death of the country.

At Fort Assinniboine, Mont., some years ago a severe epidemic of fever occurred, and it was shown subsequently that the infection was brought by the water (Beaver Creek) which had been infected by Indians

and half-breeds camped on its banks a mile or two above the fort, one or more of these people dying of the disease. In this case there was considerable irritation shown by the officer having charge of the water supply, at the imputation that the water was at fault. He stated with great vehemence that there was not a single case of typhoid in the lot, that they were all mountain fever not due to the water. This vicious term, then, actually interferes with proper sanitation in the West, and the sooner it is abolished the better.

Travel in the West is sometimes unsafe for this reason, and it is decidedly to the interest of the railroads to be positively assured of the purity of the water supplied to the cars for drinking purposes, or to have it properly sterilized if they are not certain. Entirely too often do we hear of typhoid fever occurring in persons who have been traveling in the West, and it is to the interests of all railroads to make it clear to their patrons that the water used in the cars is above suspicion.

Even in isolated places there is danger, because recent reports brought by intelligent priests and others, who have been among the Indians a great deal, show that it is not uncommon in the summer and fall, for the Indians to have a sickness which can be nothing else than typhoid fever. They do not complain much, merely lounge about their tepees for three or four weeks "out of sorts," more or less feverish, sometimes with high fever, in fact a picture of some of our cases in which the diagnosis is beyond a doubt.

Case 1.—D. E., age 22, colored recruit, one month in post. May 2, chilly sensations. May 5, Admitted to hospital. Temperature in evening over 103 for six days, then between 99 and 100 until May 26. Quinin had no effect. Widal's test, with blood, negative May 23 and 25, but with serum from blister, positive May 24 and June 2. July 4 blood gave positive reaction. June 2 this case took measles, fever lasting until June 7. The disease was derived from another recruit, who brought the infection to the post. Baths not ordered.

Case 2.—O. G., age 22, colored soldier, one year at post, was sick only three days before entering hospital June 17. Headache, limbs and joints stiff and sore. No appetite. Very slight sore throat, constipation. Fever lasted only four days November 3. Perfect Widal reaction.

Case 3.—C. T. B., colored nurse, age 24, one and one-half years at the post. May 30, had measles—contracted, as did Case 1, from recruit. Eruption June 3. June 6-8, convalescent and helped to nurse Case 1, who was brought into isolation ward with measles June 4. In these few days while susceptible to any infection, he probably became infected with typhoid, possibly from direct contact with his patient. He did not complain until June 21, when he "felt badly" and went to bed with temperature 104, next evening it was 105. He became unconscious quickly, had great subsultus, and died June 30. Had incontinence of bladder and bowels two days. Though he was in bed but nine days, the postmortem showed typical lesions of end of third week, *i. e.*, ulceration nearly completed, a few patches not having sloughed off. This case presented a picture of profound poisoning, and is extremely interesting as showing the fact so noticeable in many of these cases, that at first the patient may not have sufficient symptoms to cause him to notice them. He was doing hard work for the first ten or twelve days of the disease. Cultures from the enlarged spleen were used for Widal's test in all subsequent cases. Widal's test June 27 negative. The blood of June 28 gave an incomplete reaction in one hour, at the Surgeon-General's office, "while the majority of the bacilli had become agglutinated there were yet to be seen quite motile organisms in all fields." Fourteen cold baths were given.

Case 4.—L. B., age 25, colored soldier, one year and three months at post. Admitted to hospital August 5. Diarrhea a few days followed by constipation. Temperature above normal ten days and subnormal about one week. No data as to Widal's test. Baths not ordered.

Case 5.—S. G., colored soldier, age 22, one year at post. Admitted August 15. Headache, chill of several hours. For a few days stools were soft and of a greenish yellow, then bowels generally constipated. Fever lasted until September 9.

Widal's test August 21, negative, August 25, doubtful. (S. G. O.) "Some marginal clumping, but the majority of the bacilli actively motile at the end of one hour September 4 and 5, positive." September 23, partial reaction (agglutination and immobility not complete). Twenty-nine baths.

Case 6.—V. V., age 49, white. Admitted August 16, temperature 99.4, rising to 104 in the evening. It remained high (102 to 103) for ten days, then gradually approached the normal, which was reached in ten days more. Time of origin unknown, but he was sick for at least two weeks at Lame Deer before he entered the hospital. The nervous symptoms were very marked. In the beginning he was semi-delirious and irresponsible and destroyed a vocabulary and grammar of the Cheyenne language on which he had been at work for fifteen years. He became stupid and apathetic, careless of dress and appearances, and so mentally unbalanced that his friends brought him to the hospital for treatment of acute insanity due to worry. He was semi-comatose for fifteen days; had retention of urine, weak pulse and was not expected to live. Needed stimulation throughout. For three or four days typical "pea soup diarrhea," but subsequently there was obstinate constipation. Tongue badly coated throughout, becoming brown in third week; mouth required constant attention. There was a marked roseola. About August 20 Widal's test resulted in immediate cessation of movement but no agglutination. August 22, agglutination marked but some movement. August 31, perfect reaction. September 23, perfect reaction. Sponge bath given every two hours if temperature was over 103; about eight were required.

There was a partial aphasia in this case, which lasted well into convalescence. His memory was also defective during convalescence.

Case 7.—J. S., colored soldier, age 23. At post one year and eight months. August 17, headache; 18th, fainted in ranks; 19th, admitted to hospital; generally constipated, sometimes natural movements. Tongue slightly coated and swollen but cleared off in about fifteen days. Evening temperature over 101 for twenty-nine days, reaching normal in five more days. Eight times temperature reached 104 or over, three times it was 105. Comfortable throughout, no nervous symptoms. Quinin tried eleven days with no effect. Widal's test, August 21 doubtful, August 22 partial, August 31 positive, September 5 positive at S. G. O., September 22, positive. Considerable emaciation, convalescence rapid. Twenty-two baths were required.

Case 8.—W. B., colored soldier, age 24, two and one-half years in service and at post. August 24, chill; 25th, headache, but had "felt badly" three days. Constipation throughout disease, tongue swollen and coated; no other symptoms. Temperature variable, evening rise for eight days, once going to 104, usually 100 to 101. September 1 to 9, temperature normal. Got up September 4. September 10, temperature rose to 102.5 and remained high until September 14, when it gradually came to normal on the 21st. This was the first case in which there was a period of normal temperature (afebrile) in the middle of the course. He was perfectly comfortable throughout, and resented confinement. Widal's test September 4, partial reaction, agglutination but some movement, September 22 and 23, positive. Six baths needed.

Case 9.—R. H., colored soldier, age 24, in service twelve years and four months, at post one half year. Had a mild attack of acute melancholia in June. August 27 admitted to hospital with temperature 103.6, complained that for two weeks he had had pains in the loins, general malaise and weakness, occasional chills, and feverish at night but not in morning. Generally constipated, tongue large, pale and slightly coated. Evening temperature gradually receded from 102.5 until it reached normal in eleven days, but it varied a little for six days more. He became perfectly comfortable as soon as he was put to bed. Had slight sore throat. Widal's test, September 4 positive, though there was a slight movement of a few bacilli. Baths not needed; temperature always below 102.5 after admission.

Case 10.—B. G., colored soldier, age 22, at post one year and one month. In August was at Lame Deer, on Tongue River, where he felt badly having headaches off and on. August 21 came to Custer. August 28 admitted to hospital complaining that for three days had had sick headache and generally out of sorts. Temperature 101: on the 29th rose to 104; 30th and 31st rose to 101; September 1, 100. It then did not rise above 100 for five days. September 7, it was 100, and subsequently strictly normal. Quinin (650 mg.) was given twice or thrice daily until September 9, and seemed to cure the fever, for the temperature gradually went down. Tongue was so coated as to require mouth wash. Was perfectly comfortable throughout after he went to bed. Widal test on September 4; there

was cessation of movement but no agglutination. He went to duty September 1 feeling perfectly well. September 16 he returned as he did not seem to regain strength. Temperature normal until 29th, when it rose suddenly to 102.5, and there was a daily rise from that time on for forty-eight days when he was discharged for acute tuberculosis. Fever was always moderate (100), rarely over 101, tongue slightly coated. At first he was considered to have a relapse, for Widal's tests gave September 28 and 29, negative; October 3, positive; October 10 and 17, perfect; October 16, negative (S. G. O.). September 29 he had pains in left chest, usually near heart, worse on motion or turning over, and he had a chill that day, but nothing abnormal was discovered in the chest after repeated examinations, until October 14, when there were suspicious sounds in right apex. On 16th had night sweats and these were repeated several times. Emaciation now became greater, notwithstanding increase of food, tonics and stimulants, and November 6, there was decided involvement of both lungs and effusion in left pleura, which was absorbed within a week. Had constant cough but no sputum. Tubercle bacilli were only found once in the mucus which came from the nose and mouth. Only one bath was required.

Case 11.—R. R., colored soldier, age 25, service three months at post. Admitted August 30; complained he was sick two days; had been at Lame Deer, on Tongue River, until two weeks previously. Had headache, was tired and had pains in his legs. Tongue coated and swollen. Temperature 102.2. Evening temperature was between 102 and 103 for nine days and gradually came to normal in fourteen days more. Was obstinately constipated throughout. Widal's test September 4, immobility but no agglutination; 21st, negative. Three baths were given.

Case 12.—J. H., colored soldier, age 23, one year and one month in service and at post. September 11 had stiff neck, pains in chest, dizziness and fever, but by 15th these left and he complained of malaise, anorexia and occasional vomiting. September 15, was admitted to hospital. Temperature 102: evening temperature remained between 104 and 105 six days and 103 three days; it gradually came down for eleven days, and then was quite irregular for nine days more, when it remained normal, except one rise to 101.2 on the third day of convalescence. Was obstinately constipated throughout. Tongue heavily coated until fourth week. Tympanites first four days with gurgling in right iliac fossa. Turpentine stupe required on third day. A loud systolic murmur heard at apex for a few days. Temperature subnormal throughout convalescence. Widal's test gave perfect reaction September 22 and 23, and October 10, 16 (S. G. O.) and 17. Twenty baths were given.

Case 13.—L. H., colored soldier, age 22, one and one-half years in service and at post. September 13 had a chill, dizziness and "smothering spell;" September 15, temperature was normal, was given laxative; September 16, morning temperature normal; evening 103.2 and was put to bed. Evening temperature then gradually came down, the normal being reached in twelve days. Was generally constipated. Tongue, which was but slightly coated at first, became heavily covered with white fur in five days. Had headache at first and "weakness in eyes." Gurgling in right iliac fossa. No other symptoms; was perfectly comfortable after the first day or two. Widal's test on September 22 and 23 gave positive reaction. Five baths were given.

Case 14.—R. B., civilian, white, age 21, one month in the vicinity. Admitted September 18; had had for two weeks malaise, headache, cramps, diarrhea and anorexia. On admission, tongue foul, tympanites, gurgling in right iliac fossa and headache. Nose bled several times during course of disease; was generally constipated; marked roseola. Temperature on admission 104.2. The evening temperature was 104.6 for two days and then gradually came to 99 in twenty-two days more, but some slight irregularities lasted for about a week longer. Tongue became brown in second week. Was comfortable and free of all symptoms after a week in bed. Widal's test September 20 and 21, positive; October 10 and 17, perfect (16th, S. G. O. positive). Twenty-four baths were given.

Case 15.—E. G., colored soldier, age 28 years, nine years and eight months in service, five years at post. September 17, began to have nose bleed, and neuralgia over eyes. The latter became so severe that he had to be taken to hospital on the 20th, pains left on the 22d and he was considered well as his temperature had been strictly normal. On the evening of 23d it suddenly rose to 102.2. The evening temperature then remained between 102 and 103.6 for eight days and then sank, reaching normal in five more days. Then for fifteen days longer it showed an irregular line oscillating between 99 and 100. In the last two weeks this case came as near to being an afebrile

type as one could well imagine. He was perfectly comfortable throughout after his headache left, and bitterly resented being confined to bed. His bowels moved regularly but were soft until fourth week when constipation set in. Widal's test October 3, negative; October 9, positive; October 16 (S. G. O.), positive; October 17, perfect. Five baths were given.

Case 16.—T. R., white, cowboy, age 32. Had been in vicinity occasionally all summer. September 23 came to hospital with morning temperature of 100.6. Had headache: coated tongue: had been feverish several days, and "out of sorts" three weeks. His bowels moved regularly once or twice daily and stools were soft, sometimes watery, pea soup variety for a day or two but subsequently yellow. The evening temperature was about 103 the first week and 102 the second and third weeks. He left the hospital on the twenty-first day (September 13) temperature 102, because he felt perfectly well and resented the cold baths and milk diet. After the first few days he was comfortable. His tongue gradually cleaned off as his temperature fell. Roseola was marked. Widal's test September 29, negative; October 4, positive; October 10, perfect. He made a perfect recovery. Eleven baths were given.

Case 17.—J. B., colored soldier, age 27 years, five years and six months in service, five years at post. September 25, admitted to hospital, temperature 98.8; complained that his "head and eyes hurt" four or five days. Cold chills at times and was somewhat feverish. His "knees would give way." Bowels had not moved often, but stools were thin and watery when they did move. Evening temperature on 25th was 104.6, and for twelve days it was between 103 and 104. It then gradually came down, reaching normal in eight days, though it showed a slight irregularity for three weeks longer. Constipation was a constant feature. Tongue was very much coated and after clearing off once it again became foul. The nervous symptoms were very marked and culminated in post-febrile insanity. He was stupid, quiet and apathetic from the start. His pulse was always slow, and markedly dicrotic in the second and third week. In the fourth week the rate varied from 50 to 55. On the nineteenth day of the fever, he had great mental confusion, loss of memory and marked delusions, though generally quiet and stupid. The stupor gradually left with the fever, but the delusions continued. His mental depression was succeeded by mental exaltation and delusions of grandeur. He became filthy and violent, requiring constant restraint. One night he had a violent maniacal outbreak. His strength returned quite rapidly and until he was restrained he had no difficulty in knocking the nurses down whenever he wished. Widal's test September 28, partial; 29th, negative; October 3, positive; October 10 and 17, perfect; October 16, positive (S. G. O.). Twenty-two baths were given. The insanity might be called "confusional." When last heard from he was recovering.

Case 18.—W. P., colored soldier, age 34, nine years and six months in service, five years at post. September 25 admitted to hospital, temperature normal. Had general malaise and weakness for two weeks, felt as though "legs were drunk." Evening temperature on 25th was 103; 26th, 101; 27th, 99.6; 28th, normal, and no subsequent irregularity. There were positively no symptoms in his case beyond the three days of fever, after he went to bed. Widal's test September 28 and 29, and October 3, negative. It was considered simple fever from unknown causes. The diagnosis was changed on November 3, because on that day his blood gave a typical reaction. This case is remarkable for its shortness, the probable length of time he kept about without symptoms (resembling Cases 2 and 3) and the length of time before Widal's reaction was found. It was necessary to give but one bath.

Case 19.—R. G., colored soldier, age 26 years, four years and three months in service and at post. October 5 was admitted to hospital; temperature 101; complaining of headache and backache with sore throat. Had been sick four or five days. His bowels had been regular, and though they did not move often (once or twice daily) the stools were usually thin, watery and yellow. He was never constipated. The pharyngitis lasted about one week. The tongue was always more or less coated; edges red, and very tremulous. The evening temperature was 104 for sixteen days, and gradually fell to 99 in ten more days; subsequently it was for twenty days sub normal, or normal, with two rises, one 101 and one 99.6. The nervous symptoms were confined wholly to marked tremor and subsultus. He was bright mentally and always comfortable. Widal's test, October 9 and 16 positive (S. G. O.); October 17 perfect. Thirty-nine baths were given. He was quite weak during convalescence.

Case 20.—B. J., colored soldier, age 24 years, one year and eight months in service and at post. October 5, in evening, he was admitted to hospital with a temperature of 103.4. Had been sick a week. Had dull headache and was drowsy. Tongue

swollen and slightly coated. Bowels regular. The temperature was irregular for six days, when it became normal and stayed normal so that he got up on the fourth day thereafter, but after he had been up three days the evening temperature began to go up until in three days (October 21) it was 104. It then kept up from 103 to 105 until November 5, when it fell to 102. November 14, it was 100; subsequently it rose again and by November 19 and 20 it was again 104, where it stayed for ten days and then gradually came to normal in six days more. Convalescence then began with sub-normal fluctuations. This case is remarkable for its afebrile interval in the second week. He required fifty-seven baths. His mind was always clear. Bowels generally constipated. There was considerable cough and expectoration. Skin became dry, rough, harsh and covered with branny scales. Widal's test was perfect on October 9, 10, 16 and 19, but on 17th it was entirely negative. October 16 negative. (S. G. O.) After the second rise of temperature in November, he had a suspicious roughening at the right apex, and had had considerable cough, but no tubercle bacilli could be found in the small amount of sputum. The nervous involvement was remarkably severe. He had throughout a persistent marked tremor of both arms, but this symptom was an exaggeration of what existed before the fever, for he has had for some time a condition resembling paralysis agitans. In the course of the fever his muscles took on a tetanoid state with "lead pipe contractions;" his face was drawn almost into the rictus sardonius of tetanus. He could not open his mouth widely, nor thrust out his tongue. The stomach would not retain food during the height of these symptoms, though he had no nausea, and the attempts to vomit caused even greater rigidity of the head muscles. December 20, Dr. D. A. Howard reports the following conditions: "paralysis and marked atrophy of certain groups of muscles as follows: Extensors of hand causing drop wrist; the interossei and smaller hand muscles giving the hand appearance of a claw; 'drop foot' also present; extensors of toes paralyzed and toes are held stiffly contracted in extreme flexion; foot and whole leg, right side, atrophied to marked extent; arm also same side; angle of mouth on right side lower, and on laughing is immobile, showing paralysis; tongue pushed toward the paralyzed side; no atrophy here noted: deep reflexes (tendon) retained; no ptosis or pupillary symptoms. In right foot there is some tenderness to touch, but no edema nor congestion; no areas of anesthesia. Right hand and arm is in continuous tremor; has been so since early in the disease. No disturbance of speech, vision or hearing." On the 23d he had some numbness in toes of right foot and has cold feeling in left foot. On the 25th he could walk with some difficulty, and on January 10 he had such marked improvement in walking and was gaining in weight so much that he was transferred to his new station, convalescent. The multiple neuritis thus described as a complication of convalescence may have had its beginning much earlier, but the nervous symptoms in the course of the fever could easily have been caused by the direct intoxication.

Case 21.—O. L., colored soldier, age 22 years, in service and at post one year and two months: Was admitted to hospital evening of October 5; temperature 102.2. Had been sick a week. Had headache and constipation. Tongue was slightly coated. In two days he was perfectly comfortable and remained so. He remained constipated and the movements were hard unless a laxative was taken. The tongue was badly coated and did not clear up until the fever left. The evening temperature was 102.2, October 6; 101 on 7th; about 100 for seven days and then kept about 99 for fifteen days longer. It can not be said to have been normal until November 3, or twenty-eight days from onset. It was as perfect a type of afebrile, or nearly afebrile typhoid, as we have. Widal's test, October 10 positive; October 16 good grouping, but a little remaining movement in center of drop. October 16 positive. (S. G. O.) No baths were necessary.

Case 22.—J. C., colored soldier, age 24; only been two months in service and at post. October 4 had stiff neck pains in side and neck, and headache. October 6 fever in the evening. Had been complaining for a week or more of a bad feeling, and a pain over eyes when he raised them. Bowels were loose, but not many movements. Tongue nearly clear. October 7 was put to bed; temperature 100. The evening temperature was 102.8, coming down to 102 on the 12th, and then gradually falling to normal on the 20th; it was the slightly sub-normal twelve days and irregular for another week, but not varying more than a degree either side of the normal limits. October 12th (fifth day in hospital) there began a sharp attack of tympautes, which with its enormous hard distension of the abdomen, excruciating pain, tenderness over right iliac fossa and heart failure, was thought at the time to be peritonitis. Under saline laxatives, turpentine en-

mata and stupor, and hot local applications it gradually subsided, but the tenderness over the cecum did not leave until the ninth day. It had not a particle of effect upon the temperature, which gradually subsided all this time. He made an uneventful recovery. Widal's test gave, October 9 and 16 positive. (S.G.O.) October 17 immediate immobility, but no grouping; October 19 perfect reaction. One bath was needed.

Case 23.—J. E., colored soldier, age 24, one year and ten months in service and at post. October 7 admitted to hospital. Had been "feeling bad" for three days; general pains in head, eyes, calves and shoulders. Bowels regular. Had been feverish. Tongue heavily coated and swollen. Evening temperature was 101.4, but it rose no higher, gradually coming to normal in sixteen days. This case might have been called afebrile. After he was in bed thirty-six hours, all his symptoms disappeared, except fever. He was perfectly comfortable and good natured and did not resent his confinement. He was almost always constipated. Widal's test gave, October 9, a little agglutination but immobility; October 10, many groups, but there was little activity; October 16 positive; October 16 positive (S.G.O.); October 17 some activity and some grouping. No baths were needed.

Case 24.—W. P., colored soldier, age 26 years, only one month in service and at post. October 8 admitted to hospital with noon temperature of 100; complained of feeling badly several days; now had pains in head and back, and general malaise. Tongue coated and did not clear up until long after fever went down. October 8, in evening, temperature was 103.6; on 9th and 10th 102; 11th and 12th it was 100, and was then normal three days. On 15th he got up, as he was apparently perfectly well. On 16th evening temperature rose suddenly to 101.1, and from that point the evening record gradually declined eleven days, and was subnormal for fourteen days more, when he left hospital, or thirty-seven days after onset. He was always comfortable; had no symptoms beyond constipation and fever. Widal's test, October 9 positive; October 16 agglutination at edges, but some motility left in center; October 16 positive, (S.G.O.); October 17 perfect. The peculiarity of this case was the early appearance of Widal's test and the peculiar afebrile interval. Eight baths were given.

Case 25.—W. D., colored soldier, age 27, four years and ten months in service and at post. October 8 came to hospital, with temperature 100.2, complaining of sore throat, pharynx congested and tonsils swollen. Had headache and backache for two days. Temperature rose to 102.2 in evening, but subsequently evening temperature receded, reaching normal in four days, but the curve for ten days was irregular, varying from 97 to 99. After October 22 it was normal. He was constipated throughout, and had no symptoms worth recording. The pharyngitis was gone before the fever. Under ordinary circumstances this would have been called a simple pharyngitis, and dismissed in four days, and the abnormal temperature chart (afebrile almost) for the next ten days would not have been discovered. But on October 9, Widal's test gave some grouping and marked immobility. October 10, negative. October 16 perfect reaction, October 16, negative S. G. O., October 17, few groups but some activity. It is probable that this is an aborted case or, like Case 3, the disease may have existed a long time before he felt any inconvenience from it. No baths were needed.

Case 26.—O. G., colored soldier, age 22, one year and two months in service and at post, September 26 to October 9 was under treatment for gonorrhea. October 9 went to duty but had to be excused from guard for headache and general bad feelings. Admitted to hospital with temperature of 102.2. His tongue became coated at once and mouth was so foul as to require special care, but was cleaned off in ten days. He was sleepless for a few nights. Bowels moved once or twice a day and stools were very soft and yellow. Subsequently he became constipated. The temperature was remarkably irregular throughout: the evening record was 104 for seven days, and then gradually receded, reaching normal in twenty-two days more (November 7). After being normal three days it was subnormal three days and then normal again. Widal's test, October 10, immobility but no grouping, October 16 and 17 positive, but groups were not numerous, October 16, positive S. G. O. Twenty two baths were given.

Case 27.—W. S., colored soldier, age 26, five years and two months in service, four years and ten months in post. October 13, admitted to hospital in A.M., temperature 100.6. Had been sick two days with headache and pains in the neck. Slight cough about a week. Tongue was pale and he had foul sweetish breath. The tongue and mouth became so foul as to need special attention. Pain in head lasted two days, after which he made no complaints whatever except of hunger. There was persistent constipation throughout. The evening temperature

on the 13th was 103.2, 14th and 15th 104, it then subsided to the normal by the 21st and remained subnormal until his discharge. From the 21st for eighteen days there was a regular daily curve with range of 2 to 3 degrees, which is extremely interesting, for it shows so well the fact that even in these afebrile cases there may be a daily range never found in healthy men, and more exaggerated perhaps than the subnormal records due to the weakness of convalescence. Widal's test, October 16, positive, S. G. O., October 16 perfect, 17th some restriction of motility but no grouping, 19th perfect reaction. Ten baths were given.

Case 28.—J. H., colored soldier, age 27, three years and nine months in service and at post. October 16 admitted to hospital, temperature 99.2. Had for two days "sore" and painful eyes and headache increased by bending over. Bowels were regular but became obstinately constipated. In twenty-four hours he was comfortable and had no symptoms other than constipation and fever. Evening temperature on 16th was 101.4, but it gradually declined until 27th (eleven days). It was then irregular and subnormal or but slightly above normal for seventeen days, the daily range being 2 to 3 degrees. Widal's test, October 17, no grouping but much restriction of movements, October 19, perfect reaction. Six baths were given.

Case 29.—J. B., white civilian teamster, age 37, several years at post. About October 4 he asked treatment for general malaise with pains in head, back and legs. Temperature was 103 and he was advised to come into hospital, but held off. After a week or so he took a leave of absence, consulted a civilian physician who told him he had mountain fever and advised him to return and enter hospital. He got some medicine, and thought a "good drunk" would cure him. October 22 or eighteen days after the diagnosis was made he was so sick that he had to come into hospital. Had had diarrhea several days, but this quickly changed to constipation. Temperature 99.8, pulse 100 and strong. Tongue coated, pain in right iliac fossa. Typic roseola. The nervous symptoms now came on quickly, first slight delirium, then semi coma; deafness persisted about ten days; marked urticaria November 2, 3 and 4; paralysis of bladder November 5, requiring catheter for several days; tetanoid state of all muscles. The tongue became brown and heavily coated; mouth required constant attention. The evening temperature October 22 was 104.6; for five days it was 103, for seven days 102, becoming normal in three days more; it then remained irregularly above and below normal nine days, when November 18 it gradually rose to 102 on November 23 and reached the normal December 2—like a short relapse. It was then irregularly subnormal until he left hospital December 16. With the temperature drop November 8, all nervous symptoms gradually left. Widal's test, October 31, gave perfect reaction. Twenty one baths were given. This case illustrates the disastrous results of not going to bed at once.

Case 30.—J. C., colored recruit, age 26, three months in service and at post. October 20 he applied for treatment for headache and constipation. Was given a laxative and felt well until 26th, when he had a chill, pain in shoulders and all his bones: 26th and 27th had severe fever and 28th came in hospital; temperature 99.6. Pains diminished quickly and in three days he was comfortable. Bowels constipated. Temperature evening 28th was 101.8 and evening rise was in neighborhood of 102 for seven days, and then reached the normal in eight days more: it then became irregular, varying from 97.4 to 100.8 until November 25 when he became convalescent. It remained subnormal until he went to duty December 12. Widal's test, October 31, gave a perfect reaction. No baths were needed. He lost no strength and emaciated very little.

Case 31.—R. A., colored soldier, age 50, twenty-seven years' service, five years at post. Admitted July 1 for fever, which lasted only three days. From the general trend of his symptoms it is probable that there was a typhoid infection, but it was considered simply continued fever, and he disappeared from the post before Widal's test could be made. This test was not made while he was in hospital as it was one of the first cases, before it was suspected that an epidemic was brewing. Widal's test in February was negative.

Cases 32, 33 and 34.—Three children, ages 2¹/₂, 3¹/₂, and 5, one colored. One white child had typical roseola. The fever was moderate in height; lasted two to three weeks; was uninfluenced by quinin in one case and the drug was not given in the others.

Case 35.—M., female, age 45, typic roseola. She was seen but once and then only after she had been sick two weeks with fever. She recovered in about two weeks more, but the course was mild; constipated; tongue coated.

The following peculiar case has not been included as it was impossible to get facts:

B., colored recruit, admitted November 8 for adenitis of left groin. He had been in the post one month. Claimed the bubo had existed only two days, but he was so evidently lying that it was suspected that he had been sick a long time, but was afraid to ask for treatment, fearing dishonorable discharge for concealing a venereal disease. Temperature was 103, and stayed up for five days. Suppurative gland was excised November 9. On the 11th his condition was so identical with the other cases that his blood was examined by Widal's test and a typic reaction obtained. His temperature remained normal after the fifth day and in ten days he was sent to another post. He claimed that he never had had typhoid fever but his statements were too unreliable to be accepted.

ANALYSIS OF CASES.

A study of these cases brings to light the following facts and deductions.

Prodromes.—The usual malaise and headache are almost universal; in a smaller number the pains are present in other parts of the body, commonly in the back. Nose bleed never occurred as a prodrome. In one or two cases it occurred during the course of the fever.

SYMPTOMS.

Constipation is almost the rule, only in the severe cases do we get diarrhea, and only very rarely is the stool of the typic pea-soup variety. The cases being mild, illustrate the rule throughout the world, that constipated cases are not to be feared. The abdomen is rarely distended, only one marked case.

The roseola was present in every white case, mild or severe.

The breath was always foul, yet of a sweetish odor.

Perspiration.—The foul sweetish odor of the perspiration was so constantly present as to be pathognomonic. It was almost possible to pick out the typhoids in the ward from the odor of the patients. Perspiration was rarely abundant.

The headache seldom lasted more than two days; as a rule it was gone after twenty-four hours in bed.

Pharyngitis and bronchitis were rare.

The pulse was markedly dicrotic in but one case, No. 17. The rapidity of the pulse, though never marked, was increased in proportion to the rise in temperature.

The tongue was always coated. In the mildest cases there was a whitish fur along the center of the dorsum, the edges and tip being clean. This coating was more marked in proportion to the severity of the cases, and in the most severe it was brown and extended over the whole dorsum of the tongue.

Temperature.—Some of the cases present a chart in no way different from the typhoids found elsewhere. The greatest peculiarity is found in the few cases in which there was a distinct period of normal temperature in the course of the disease. From the fact that the disease can exist nearly two weeks without symptoms as in the fatal case (No. 3), it is quite possible that those recrudescences may be true relapses. Some cases are nearly subnormal and afebrile, though in every case there was a period of fever, perhaps of only a few days. It seems that these few cases are as near an approach to those sometimes found in Europe as we may well expect. In two cases there was not a regular daily rise and fall, but it took two or more drops daily, one record might be 104 and the next nearly normal, and so on every three hours, and this in the first or second week. The slight elevations in the fifth and sixth weeks of the protracted cases are believed to be due to the anemia, weakness and possibly nervous causes.

Spleen.—The spleen was enlarged as a rule, but it

was distinctly palpable in only three cases, each of them being severe.

Nervous symptoms.—As a rule, nervous symptoms were conspicuous by their absence. Some of this was no doubt due to the cold bath treatment. In the few cases in which they were marked the patients had been up and about during the first week or two. One of these had traveled 100 miles in a wagon a week previous to admission, another had been on a spree, and the third (fatal) had no symptoms for eleven or twelve days (ambulatory type). In the others the symptoms were not marked and in only two of these was there delirium. Tremor was present in two. The peculiar tetanoid state found in three was characterized by the "lead-pipe" symptom, that is, each joint resisted movement but stayed in the position in which it was bent. It is quite similar to the same symptom found in some cases of cerebral or spinal palsies. Paralysis of the bladder occurred in only two and they were severe cases in white men. Partial aphasia occurred in one case.

Complications.—Bronchitis was rare, only three or four cases. There was no pneumonia. Intestinal hemorrhage was several times suspected from sudden falls of temperature, but in no case did blood appear in the stools.

Sequelæ.—Tuberculosis occurred in one case and in one there was post-typhoid insanity. In but four cases was there extreme emaciation as a result from the fever. There were no bone lesions, abscesses and other local sequelæ due to the bacillus. Multiple neuritis occurred in one case.

Mortality.—Only one death in thirty-five cases is not remarkable when we consider the mildness of many cases and the fact that the great majority were put to bed at the very beginning of the disease. The benefit of early confinement to bed has repeatedly been noted in typhoid fever. The fatal case was an ambulatory one, still further proving the benefit of early treatment. The condition as to nourishment also has a vast influence on the course and mortality. In one epidemic in the southwest which has been described as mountain fever there were so many taken sick as to stop all work in a military post, and yet not one soldier died, and the only death in the post was an ill-nourished, old civilian employe. Outside of the post the Indians were infected in equal numbers and as they were ill-fed and badly nourished they died in large numbers. Nevertheless in other epidemics, likewise called mountain fever, the mortality among robust, well-nourished soldiers is said to have been remarkably severe, as at a cantonment on the Uncompahgre, in 1881, in which the infection very likely came from the Indians also.

Widal's test.—Widal's test gave a reaction in every case (except one) in which it was tried. It will be noticed: 1. That as a rule in the first week or two the reaction was absent or was incomplete, that is the agglutination was not perfect except perhaps at the edges of the drop, and that there were some bacilli still actively motile at the end of one hour. In the latter part of the disease the reaction was perfect in almost every case. 2. As a rule the more severe the case, *i. e.*, the higher the temperature or the nearer the case resembled typic typhoid, the sooner was the reaction obtained and the more perfect did it appear. The milder the case was, the more imperfect did the reaction appear until quite late in the disease. In one case (18) it was not found until after convales-

cence. In this form of typhoid then, Widal's test is worthless for diagnostic purposes in the earlier stages. The absence of Widal's reaction in the early course of these cases probably explains abortive cases of unknown fever in the east, such as those described by Dr. N. E. Brill in the *New York Medical Journal*, Jan. 8, 1898. In these cases there were typhoid symptoms but no reaction to the test. The tests made at Custer with cultures from the spleen of the fatal case (3) were almost identical in results with those made at the Surgeon-General's office.

The results can be explained by the supposition that there was not much intoxication and that the special substances causing Widal's reaction were very slowly formed. This supposition is in strict accordance with the symptoms and general course of these cases. Indeed in Case 3 there were no symptoms whatever in the first eleven or twelve days of what proved to be a fatal case. Negroes are said to give reaction normally, but we never found it so except in one case, who on previous tests gave a negative result; a healthy negro or one not suffering with typhoid was used as a control every day.

Roseola.—All the cases except eight were in negroes, consequently the roseola could not be seen, but in every white case the typical rose rash was present. The most marked rash found was in a child 2 years old, who was so slightly ill that she could not be confined to bed. Her fever lasted about twenty days.

Urticaria.—A general urticaria in Case 29 lasted several days during the height of the fever.

Diagnosis.—Malaria was excluded by the failure of quinin and by the presence of Widal's test in every case except one, and the failure of the test in all other negroes except one. Blood was examined in a few cases for the plasmodium, but it was not found. Then, again, recovery took place without quinin, and in every white case the roseola was present. Unfortunately, we were not so situated as to get the bacilli from the stools and urine and demonstrate them.

The presence of western fevers is complicated with the presence of undoubted thermic fevers during the hot season. In these elevated lands the atmosphere is clear and cloudless and the sun's rays pour down a torrent of heat, which would surely be quickly fatal were it not for the dryness of the air, which permits an enormous invisible evaporation from the skin. The loss of heat is not enough at times and a condition of fever results, but the typical sunstroke is almost unknown. If the patient goes to bed the fever lasts only from one to four days, and no medicine seems to be a specific for it. Unfortunately, the cases on which these statements are based were seen before the cold bath treatment of all fevers had become so well known, or it would have been tried, and reasoning from analogy we can rest assured that there will be a rapid, almost instantaneous, recovery if it is used in these short thermic fevers. But to call a simple fever of unknown cause of over a week's duration anything but typhoid is apt to be an error. We have shown (Case 3) how a case may be fatal, yet for the first twelve days give no symptoms whatever.

Those who claim there is a new disease must prove it, or they are guilty of criminal conduct in permitting the spread of a dangerous infection. The safety of the community demands that they be considered infectious.

An editorial in the *JOURNAL OF THE AMERICAN MED-*

ICAL ASSOCIATION Jan. 1 1898, gives a synopsis of the numerous atypic forms of typhoid fever. The lesions may be confined to any portion of the intestine, even the stomach or large bowel, and may be of any grade of severity, or they may be entirely absent from the canal and lesions confined to lymph nodes and spleen, and there may be a true typhoid septicemia without lesions. Any organ may become infected, usually as a complication, but sometimes as the sole lesion, such as typhoid abscesses of the pleura, lung, thyroid gland, peritoneum, parotid gland, biliary passages, kidneys, testicles, periosteum, bone marrow, joints, skin, subcutaneous tissues, meninges, endocardium and middle ear and heart muscles. Mountain fever is merely one of the myriad forms of this infection. It is to be hoped that all Western fevers will be subjected to Widal's test. M. Taty, in *Lyon Medical*, November 7 (*New York Medical Journal*, Dec. 4, 1897) refers to the delirium or insanity of typhoid which may mask all other symptoms and even cause cases to be sent to a hospital for insanity, as in Case 6 of our series. Widal's test has been of incalculable value to sanitary science in thus showing how wrong we have been in refusing to recognize typhoid unless the patient was sick a long time with typical symptoms of the classic type.

Source of infection.—As before mentioned, it is quite evident that typhoid is endemic in the Indian tribes of the West—it may be fatal for all we know, because the Indians rarely call for medical advice in such cases. They either endure it stolidly or call for the tribe's "medicine man." It is possible that western rivers have always been infected with typhoid from Indians, and we have here a logical explanation of the sporadic cases of typhoid now and then reported from isolated places in the West, tending to prove the origin of typhoid *de novo*, a thing yet undetermined. In this epidemic sewage entered the water-supply, and as the writer saw a case of typhoid whose discharges had gone through that sewer, and as there were numerous other mild cases at the same place, the origin of our infection is quite evident. Two (Cases 6 and 10) were infected at Lame Deer, sixty miles from Custer, where there was considerable typhoid. The introduction of the above sewer was seriously protested, but it went in nevertheless, and it took just eighteen months to prove that the protest was just. In the meantime one man is dead—an unnecessary death.

Time of arrival at post.—The time at which the cases arrived at the post throws some light on the source of infection. For instance, Case 1 was taken sick one month after his arrival. This and a few others show the susceptibility of new-comers. Case 24 was a recruit of only one month's service, and Case 14, civilian, was taken ill only two weeks after he arrived; Case 24 two months, Case 11 three months, Case 30 four months and Case 9 six months. In every one of these cases malaria can be positively excluded, as quinin was not required and Widal's test was present and the course of the disease or its complications left no doubt as to the diagnosis; in only one (11) did the Widal test prove not conclusive. All the other cases had resided at the post over one year. Cases 2 and 5 one year, Cases 10, 12 and 13 one and one-twelfth years, Cases 21 and 26 one and two-twelfth years, Case 4 one and three-twelfths, Case 3 one and six-twelfths, Cases 7 and 20 one and eight-twelfths, Case 23 one and ten-twelfths, Case 8 two and six-twelfths,

Case 28 three and nine-twelfths, Cases 19, 25 and 27 over four years, Cases 15, 17 and 18 over five years, Cases 16 and 19 several years and Case 6 fifteen years. Malaria can reasonably be excluded on this alone. In none of these latter cases could the infection have been received except here or at Lame Deer. They did not bring it from the East and it did not originate spontaneously.

Treatment.—Quinin was tried faithfully at first, but having no visible effect it was stopped as a waste of a good drug. Subsequent cases received no medicine except laxatives and stimulants when necessary. Diet was limited to milk, 180 c.c., every three hours day and night. It was well borne by every case, even by one man who claimed that he never could drink it. Broths were given as soon as the temperature began to seek the normal, and then there was a gradual addition of eggs and soft food. Meat was withheld until the temperature had been normal at least ten days, sometimes longer in the afebrile and subnormal cases. The cold bath treatment was carried out faithfully in every case. After some variation a rule was made to tub for fifteen to twenty minutes every three hours that the temperature was over 102.5 with water at 75 degrees. There was a reduction of temperature after the bath of from 1.5 to 4 degrees or even more in some cases; lack of nurses prevented an accurate record being kept of these observations. The earlier the commencement of treatment the milder the case as a rule. The number of baths required varied greatly. Twenty-six cases were ordered baths; but of these, five (Cases 9, 21, 23, 25 and 30) required none, three (Cases 10, 18 and 21) had one bath, Case 2 had three, Cases 13 and 15 had five, Cases 6 and 25 had six, Case 24 had eight, Case 27 had 10, Case 16 had eleven, Case 3 (fatal) had fourteen, Case 12 had twenty, Case 29 had twenty-one, Cases 7, 17 and 26 had twenty-two, Case 14 had twenty-four, Case 5 had twenty-nine, Case 19 had thirty-nine and Case 20 had fifty-seven.

Thermograms.—The temperatures were taken every two, three or four hours according as we had nurses to do it, consequently the thermograms are not uniform. They have been reduced in size so as to be easily compared and the curves explain themselves. On the charts four spaces are taken for each day and the records are so charted as to show the time of day, for instance, 6 A.M., noon and 6 P.M. being on the lines, while 3 A.M., 9 A.M., 3 P.M. and 9 P.M. being between the lines, and appropriate positions given to 4 and 8 P.M. This is to avoid writing the times for each record. Sometimes as many as twelve records are crowded into one day, but these show quite graphically the remarkable fluctuations which now and then occur. The rapid and sudden drops recorded are due almost entirely to the cold baths, for the temperature would sometimes remain down several hours after a bath. In the afebrile cases the curves show conclusively the sickness, for they are so different from the normal line eventually reached in every case. The highest daily record may occur at any hour of the day or night, and is not necessarily an evening exacerbation—indeed there may be two maxima one in the morning and one in the evening. In some cases, in the first week we may get the rapid fluctuations commonly found in the fourth week of ordinary typhoid, and this fact shows how a physician may be deceived in a case if he happens to visit it daily during the remission. He may find the temperature normal, yet right after he leaves it may be 104 or over.

Abortive cases.—What are called abortive cases may not be such at all, but the terminations of ambulatory cases which in the first two weeks gave no symptoms whatever. Thus Case 25 may be either a short attack or the end of a long one. In this case the chart shows an abnormal curve for twelve days after the fever left, and is identical with the termination of the longer cases. The subnormal fluctuations may be considered the usual course of typhoid convalescence, but in the short cases such as 24, it is possible for these fluctuations to represent an afebrile period in the third, fourth and fifth weeks of the disease and not the convalescence. These subnormal fluctuations, no matter whether they be considered either of the above, show that the heat-regulating centers are decidedly disturbed by poisons in the blood—and this is true even in case like 25 where the infection was so slight that fever lasted only three days. Surely an infection which disturbs these centers for two weeks is a dangerous and serious one. Thus Case 25 shows how little incommoded a man may be with typhoid fever, on the Western plains, carrying a dangerous infection to others, so slightly infected himself as to have no fever, and yet be several weeks in convalescing. An inspection of these afebrile thermograms leaves no doubt whatever of the illness of the patients—they are abnormal curves. These afebrile or abortive cases raise the suspicion that if all the abortive cases reported by Woodbridge and others be similarly investigated they will be found to have irregular subnormal fluctuations long after the fever leaves, proving that the infection lasts just as long as in the classic type of typhoid fever.

Dangers of Western fevers.—Nothing could show more conclusively the dangers of the mild Western fevers, and the utmost necessity existing to look upon them all as typhoids until they are proved to be something else, such as imported malaria. To try to discover new diseases in the West has failed before, because typhoid has not been excluded, and the sooner all such efforts are given up the better. It is indeed criminal not to take the view of the infectious nature of the disease and try to prevent further pollution of the waters, and to give these fevers any other name is only to blind us to the danger. Several years residence in Montana has proved to the writer the extreme danger of drinking water of unknown origin, and many a traveler has suffered for his temerity. It is almost a National question, for it is so important to travelers to protect them from harm. Investigation will probably show that all other fevers in the west which are now masked under other names are all atypical and therefore regular typhoids for mild typhoids are almost always atypical.

The chief danger arises from the fact that the disease may last for so long a time without symptoms, Case 3 for instance. Far better would it be to have severe symptoms at first so as to compel confinement to bed. "Walking cases" are the worst here as in the East. Then again, walking cases are spreading the disease far and wide and in time will make the Western country as bad as the East, because in these arid sections the water supplies are so few and widely separated, and so surrounded by people and open to contamination, that universal infection of the rivers is possible.

It is time that we should also try to stop the nonsense about waters purifying themselves. No doubt sunlight and other germicides do destroy immense numbers of pathogenic organisms introduced with

sewage, and no doubt, also, that harmless hardy saprophytic bacteria natural to all waters destroy the organic matters introduced in sewage, but it takes time for this, perhaps many days or weeks, and only small quantities can thus be disposed of. Hence if feces enter a stream flowing at the rate of two miles an hour, in fifteen hours people thirty miles away are in danger of swallowing the filth with their drinking water, because destruction of feces by decay brought about by saprophytes is not accomplished in anything like fifteen hours. Again it is proved that if water is muddy, preventing the penetration of sunlight, typhoid bacilli will live much longer than if the water is clear. Indeed there are many causes at work, which may prolong the life of pathogenic bacteria introduced into the stream, so that they might be carried hundreds of miles. Self-purification of rivers in the course of time may be a fact, but it is a dangerous fact, because it gives the ignorant a false idea of safety. Some laymen even believe that five miles down stream from a sewer outlet the water has "purified" itself, even though the current is five miles an hour, the time limit never entering their minds. The new crusade now being carried on throughout the world is the only logical and rational one—a crusade against polluting water courses. These streams are public property of vital importance, and he who ruins that property is a criminal. The public should punish him just as severely as it would punish a man who would deliberately pour poison into a neighbor's well.

THE PARALYSES,

BY ONE OF THE MANY PARALYTICS.

Presented to the Section on Neurology and Medical Jurisprudence, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY SAMUEL KNOX CRAWFORD, M.D., LL.D.

CHICAGO, ILL.

To have studied paralysis from clinical phenomena observed in one's own body, and to have closely watched its varied and variable phases from a subjective point of view, is to have learned well a story which too few survive to relate.

To have suffered a grave lesion of a part of one hemisphere of the central ganglion, and yet to have been fully conscious of it all, and able to interpret the nerve disturbance and mental perturbation resulting therefrom, and to have been capable, conversely, of locating the lesion from the distal nerve phenomena, is to have enjoyed a rare privilege that none would seek, and to have passed an ordeal through which few pass and survive. Surviving, they seldom possess sufficient force and energy to attempt a formulated portrayal and deductive story of the ailment suffered.

The consensus of medical opinion is to the effect that to the subject it means simply the loss of motion and sensation, and that the conditions leading up thereto are but factors of the same disease. The lost mobility and perverted or lost sensibilities are but fragments of a colossal whole. Paralysis means greatly more. It means, in most instances, pain of a most excruciating character, and mental distress almost unbearable and altogether inconceivable to all but the sufferer himself.

An analysis of the pathology obtaining in the disease leads the writer to the conviction that it is simple, however complex and complicated its etiology

may be and generally is. In all forms of the disease, in whatever dress it may present itself, there is disturbed nutrition at the central point of attack. The invasion is the result of a strangulation. In every case of the disease, without exception, from whatever original or remote cause, there is necrosis of medullary tissue. A thrombotic body is the central figure of every embolus, and an embolus or emboli form the essential condition of embolism. Embolism strangulates. Strangulation invariably results in necrosis. Necrosis of medullary matter will invariably result in paralysis of the parts supplied by the nerve trunks whose origin lie within the field of necrosed tissue.

Whatever the primitive step in the morbid process there is strangulation, the result of pressure followed by necrosis as a sequence. An endocarditis leaves a valvular insufficiency. Valvular insufficiency conduces to the formation of pedicular thrombi. A thrombus breaks its pedicle and cuts loose from its moorings and floats with the current of blood to the brain or spinal cord till it reaches an arteriole whose lumen is too small to admit of its free passage, and there it at once becomes engaged and an embolus is born and embolism begins. The volume of blood in the part is impeded, a blood clot is formed and death of tissue ensues.

When an electric battery has its generative function suspended there can be no current at the distal extremity of the conducting medium. Equally true is it, that when any part of the brain shall have had its nutritive functions impaired, interrupted or suspended, there can be no nerve force or current at the distal extremity of the trunk whose origin falls within the area of disturbed nutrition in exact proportion to the degree of disturbance. Neither can there be impressions received at the point affected from the periphery, save in the same ratio of the intensity and extent of the morbid action. Thus there is the chain of circumstances obtaining in paralysis complete. It would seem, therefore, apparent to the casual observer that when the initial symptom of brain clot appears, the physician's imperative duty is to circumvent further pressure and reduce if possible that which may have already transpired.

A blood clot in the brain, from whatever cause, always continues to increase in volume until a collateral circulation shall have been established, unless in some way the blood can have its intensity and forceful activity brought under subjection. The larger the clot, the greater the area of section of suspended nutrition will obtain, and the more extended, therefore, will be the phenomena of suspended function in distal parts. If when an embolism first occurs, as shown by the earliest phenomena, the force and activity of the blood current be subdued or modified, the least possible amount of pressure and the resultant strangulation, and therefore the least extent of necrosed tissue and its long chain of morbid phenomena will have been obtained.

Our own lamented Gross's "lost art," if employed at the beginning, would be the eminently proper remedy, and this to be supplemented by the employment of some well known and reliable cardiac sedatives or more properly speaking, nerve sedatives and cardiac depressants. After the circulation shall have been duly subdued, the work of promoting rapid absorption should be efficiently begun and prosecuted by every means at command. Prominent among these measures the writer believes the electric current to

stand first, and medicaments such as strychnia and cactus, to give force to the vasomotor powers of the fabric. It is possible for brain and nerve tissue to be renewed when once destroyed, and nature is quite willing and ever ready to begin the process of repair at once if she be properly assisted. She should be encouraged in her efforts by all known means. Hope, that greatest of all regenerative forces, should be established at once by all possible measures, and the will to do and live should be called into play. These two greatest of all recuperative forces are singularly overcome in all cases of apoplexy.

Suggestive hypnosis is no mean allied measure to employ in all cases of paralysis and should in no case be neglected. Memory may be, and sometimes is, either quite lost or perverted for a time; but on the contrary, it may be and often is quickened and even permanently brightened. In some cases aphasia is a prominent symptom, but in others the use of language is increased to a remarkable extent, and in a peculiarly interesting manner. Forgotten and long neglected languages have been recalled with astonishing clearness by not a few paralytics. The intellect in a general way is improved in some to a notable degree, in that the powers of arrangement and detail are made especially strong. The power of elimination, where never before in evidence, is in some made manifestly strong.

Can an apoplectic locate the lesion and pressure in his own brain by common sensations? Yes. Never was a boil in the axilla more easily located than was the pressure spot in the writer's brain by his common sensibilities. He could have guided the surgeon's knife to the exact spot where the clot pressure obtained, with as unerring a hand as he ever sought a ball in a soldier's brain. He longed and prayed for an opportunity for an object lesson in this.

Scientific surgery has a great work pending for the coming twentieth century, when it shall have left the pelvic and abdominal cavities and strayed higher where vitality rules in the thoracic and cranial cavities. One of the finest and first object lessons the writer ever enjoyed was that of the removal of bone, two and one-half by three inches, from the right parietal region of a 14 year old boy, through which stellated fracture fully half a teacup full of brain matter had escaped during the interim between injury and operation. This was in January, 1862, and in May, 1897, when last seen, the subject was a hale and hearty farmer, 49 years of age, who has enjoyed uninterrupted good health in every way since the operation, and has been eminently successful in his business enterprises. The bone has manifestly long since been renewed and there has been nothing in evidence to show that the lost medullary was not impaired. This refutes the somewhat prevalent notion that cranial bone once destroyed will never be renewed, and brain matter once lost will not appear again.

The Röntgen electric ray, which has so marvelously outdone opacity, is destined to play no insignificant part in the surgery of the thoracic and cranial cavities, and the day when a clot or abscess in the brain or thoracic viscera will be readily located and relieved, is not far away. The physician, too, must not be found loitering by the waysides of ignorance and superstition, and contenting himself with looking wise and scratching off, in his peculiarly fascinating way and hieroglyphics, a prescription for some remarkable placebo. He must bestir himself and feed the organ-

ism with foods proper for the rapid and certain nutrition of the brain and general nervous system, and study well the best methods of promoting the assimilative functions in any given set or class of organs. He must contrive to supply the proper substitute for the interrupted nerve current by the employment, in a scientific way, of the electric currents and by observing polarity and studying its laws, and must familiarize himself with dosage in the case of electricity as in the case of any other efficient and valuable remedy. He must take the measures of this imponderable agent with the same celerity and accuracy with which he would use the apothecary's scales, and then he will have less but better use for his urinometer and thermometer, and do much that he now leaves for the surgeon to accomplish. He must more carefully and critically study the stomach, the accomplished laboratory of the animal fabric, and learn to change an alkalinity to a proper acidity of this principal chemical mortar in the twinkling of an eye, by the polarized current.

If he do these things he will malign the poor old liver less and become less familiar with the word dyspepsia.

He will thus have learned a method of supplying nourishment for any organ or set of organs in the economy, through the natural and proper channel, to be assimilated, which is the last essential of the long chain of acts in the function of nutrition, beginning with prehension, which he never knew before. But he will supplement these suggestions by supplying more oxygen in the form of gas by inhalation, and oxygenated water by inhibition, than can be supplied by nature through ordinary channels and in the usual way. He must learn to fully understand that oxygen, the great vitalizing element as well as the supporter of combustion, which is after all the method which nature has devised for sustaining an equable temperature of this great thinking, talking, walking, working and living machinery of ours, is always in demand. He must learn to adopt nature's own plans and measures more than he now does; and if so he will have become more truly a practitioner of preventive and curative medicine, the highest function to which science may attain, and which conduces to the highest interest and hopes of humanity.

DISCUSSION.

DR. LODER—Will Dr. Crawford give us a description of the sensations which preceded and were co-ordinated with the lesion, as it might be some guide to us in locating such lesions and also in asking patients questions.

DR. CRAWFORD—The feeling that I had about an inch and a half back of the right ear, deeply located, was very similar to a toothache. Total paralysis of the left side resulted. I had anesthesia and loss of sensation in the leg. The sensation was that of wedging in, and there was no sharp pain at the location of the trauma. For four months I had severe continuous pain throughout the side. The pain was most severe just below the left hip.

DR. DERCUM—It is not impossible that there should be some sensation of a very generalized character noticeable by those patients whose consciousness is preserved. Neuritic pains rarely, but sometimes, occur in hemiplegics. Peripheral pain in hemiplegics does occur in some cases.

Request your Congressmen and Senators to fight the Caffery bill!

INTERNAL CEREBRAL MENINGITIS CHRONICA; NOTES ON DIAG- NOSIS AND TREATMENT.

Presented to the Section on Neurology and Medical Jurisprudence,
at the Forty-eighth Annual Meeting of the American Medical
Association, held at Philadelphia, June 1-4, 1897.

BY ELMORE S. PETTYJOHN, M.D.

MEDICAL SUPERINTENDENT ALMA SANITARIUM.
ALMA, MICH.

The practical importance to both physician and patient, the seeming lack of appreciation of its frequency in the most unsuspected cases and the desire to emphasize the necessity of early recognition, diagnosis and active treatment of this always grave disease, are the considerations that have led to the presentation of this subject.

Specific infection is the common and chief cause of chronic internal cerebral meningitis, chronic meningo-encephalitis and the various forms of endarteritis and peri-arteritis. This poison is prone to attack the cerebral meninges and vessels, and these pathologic conditions are seldom found in the absence of this infection. Belonging, as it does, to that class of chronic affections whose phases and results extend over many years, this disease is nearly always produced by the luetic virus, which is one of the most energetic and surely operative known in the study of disease.

It is an undisputed fact that this specific infection is widespread and even increasing. Not only in Russia, Prussia, Portugal and the Sandwich Islands, is this disease as a constitutional malady found to affect directly or indirectly a large percentage of the population (endemic in 90 per cent. of the villages of the Novgorod, according to Ostroumoff, and 10 per cent. of all the patients of physicians of the Sartov Society), and according to the careful authoritative estimates for classic Berlin, one-tenth of the entire male population is infected; but at the present rate of increase of this calamitous disease in this country, the same estimate may soon apply to New York, Chicago and other of our large cities. While epidemics do not now occur, owing to our increased knowledge of the symptoms and treatment, individual instances of the transmission of this disease both by the immediate and mediate methods are multiplying.

By a careful study of the statistics from Hjelman, Diday, Hutchinson, Kassowitz, Fournier and others, it is estimated that of adult patients with this disease from 2.5 to 6 per cent. have the cerebral form, much less rare than Dr. Clouston would have us believe.

In general, the symptoms of chronic internal cerebral meningitis vary according to the situation and extent of the local lesion. It is conceded that the constitutional infection may give rise to an acute meningitis or meningo-encephalitis in the absence of any distinctive specific lesion that has been discoverable. The symptoms would then be the same as of acute meningitis from other causes. The diagnosis of this chronic or acute infection is very easy when you get the history of the specific lesion, sore, eruption or cicatrix or when exposure is known or admitted. But the absence of these or their oversight on the part of the patient makes the difficulty very great. Even the identification of the meningitic changes (postmortem) as the invariable result of this infection, according to Sternberg and Heubner, give us no aid in diagnosis. An external pachymeningitis may undoubtedly exist for years and possibly be congenital,

without giving marked symptoms, and remain latent until by some exciting cause, such as acute disease, alcoholic excesses, over-study, anxiety and worry, the internal layer of the dura mater is reached and the soft membranes begin to show active symptoms of such inflammation.

It is at this time that we should be able to recognize the condition and by following the train of symptoms reach a correct diagnosis. The implication of the pia mater interferes with the circulation and nutrition of the cortex, and changes in the cerebral function make their appearance. At this degree of development of the disease the true condition is liable to be confounded with the functional neuroses, nervous prostration and even epilepsy, owing to the transitory nature of the focal symptoms. In the latent condition developed by the exciting cause, or anywhere in the entire course of the disease, from the first three weeks to twelve or sixteen years, these prolific changes, involving the meninges and blood vessels in the cord as well as in the brain, may manifest themselves in utter disregard of the arbitrary classification into "stages," which I believe to so intermingle as to make such classification inconsistent in most cases.

The single symptom common to all the rapidly variable and irregular features of this condition, is pain in the head, which may precede more pronounced cerebral symptoms by days, months or even years. While this pain may not seem to differ from headaches due to other causes, it can be discriminated. It may be referred to the frontal region, or to the one or the other parietal region, or even alternate. Since it is an expression of lesion of the meninges, it is more diffuse and more deeply seated than a pain dependent on a bony lesion or an ordinary neuralgia. A sense of weight or fulness, or tension with occasional explosions as if the cranium would split, are peculiar to this condition. There is an habitual intensity about it which is distinctly periodic. There are nocturnal exacerbations. There is obstinate insomnia unrelieved by anything save convulsion or paralysis. This symptom may last for years, may be better on arising or after food, but persistently returns with original or increased intensity. If there were no others, I should consider this symptom pathognomonic.

Sleeplessness prolonged and persistent, without any evident cause and unrelieved by hygienic measures or aught else save convulsions or paralysis, is an important symptom. Polydipsia and polyuria in the absence of sugar or morphologic elements are of great diagnostic value. Muddy whiteleather complexion or marked anemia with 50 or 60 per cent. hemoglobin and less than 3,500,000 of red corpuscles are noticeable indications of this infection, especially if the hemoglobin and red corpuscles do not increase with exhibition of iron preparations. With these symptoms infection may be assumed. The peculiar psychic phase is extremely important. The patient in prime of life or younger is unable to read, loses interest in his business or the affairs of life, is indifferent to his own interests and inconsiderate of others; his intelligence is blunted or confused, he lacks power of concentration, makes errors in judgment, becomes irritable, easily excited and cross, is at times erratic, opinionated and peculiar. This accumulation of alteration of thought and conduct seems peculiar to meningeal inflammation.

There is usually inequality of the pupils and sluggish reaction or failure of response to light and accom-

modation. The optic disc reveals venous engorgement and the various stages of atrophy. There is a fleeting hemianopsia and reduction of the field of vision. There are focal epileptiform explosions both motor and sensory. Epilepsy may develop after 21 years of age, as in a case now under the writer's care. Aphasias or monoplegias in any form in young persons, developing suddenly or slowly, independently of any traumatism, with a tendency for any or all of these symptoms to improve spontaneously and relapse, belong to this condition. A combination of any or all of these symptoms may occur without any recognition of the infection on either the skin or mucous membrane and in the absence of demonstration of the etiology, that is, a recognized and acknowledged infection. With these clinical facts added to the above, specific infection may be affirmed.

In general, the prognosis is favorable when the disease is recognized before secondary sclerotic conditions have become permanent, which we know are beyond the reach of therapeutics. Cases where the onset is sudden are more amenable to treatment than where the commencement is gradual and insidious. As different persons react differently to the infection and respond differently to treatment, each case is separate.

The preparations of iodine have the power of influencing the specific products by resolution and elimination, but are not antispecific. The iodide of potassium should be given to the physiologic limit of toleration of the patient. While the sodium salt is at times better tolerated, it is a less powerful alterative. From 2 to 13 grams *per diem* of the potassium salt may be administered in hot water or milk, or in alkaline effervescent waters. In giving tentative treatment, the larger doses seem better tolerated in many cases, and create less disturbance than the smaller quantity.

Mercurial treatment should be instituted as soon as the diagnosis is established, be applied with great energy and carried out for three or four years, alternating the very active and mild courses at intervals of four weeks, according to the tolerance of the case. This disease should always receive a chronic course of treatment. Mercury alone seems to be regarded as the sole specific for the virus itself. It may be administered by the method of Hutchinson, hydrarg. cum creta gram 0.065, Dover's powder gram 0.065, four to six times daily; by the biniodide or proto-iodide in pill, or in the preparation known as mercauro, which often agrees best with the stomach and is a tonic besides. Where it is practicable I believe injunction to be the more effective means, as it reserves the stomach for the systemic tonics and nutritious foods so essential to the system undergoing such abundant tissue change for so long a period.

Grams 4 (daily for thirty treatments) of mercurial ointment rubbed slowly into the inner surface of the thighs, under the arms, on the sides and the chest, over the abdomen and across the lumbar region, selecting a different place each treatment, is the quickest, safest and best method of administration. The drug penetrates the subcutaneous tissue, is transformed into soluble albuminoids which destroys the power of the specific virus. It is then eliminated through the capillaries of the salivary glands and skin, and the mucous membrane of the mouth, stomach, liver, kidneys and bowels. On first sign of irritation in the mouth, as sponginess of the gums or ropiness of the saliva, the treatment should cease for a week and the

patient should use a mouth wash containing a tincture of myrrh or rhatany.

Where there are indications therefor, when inunctions fail or can not be given, the corrosive chlorid, the most soluble salt, combined with urea gives excellent results. If calomel, which is less soluble, is thus given, symptoms of saturation may occur and continue, as it is impossible to prevent the further absorption of the remedy.

Then baths daily are serviceable for an active line of treatment as a means of hastening and encouraging the elimination of both the iodides and mercury from the body. Hydrotherapeutics as an adjunct to keeping the patient in better health is of advantage, in that more of the remedies can be given and eliminated in the same length of treatment.

Notwithstanding Dr. H. A. Hare's claim, that neither the meninges nor cerebrum are affected by the electric current, I believe galvanization of the brain to be a valuable adjunct to the treatment of this condition except in the acute febrile form. Eight to ten milliamperes of current can be safely used, and even more, to continue for fifteen minutes with a daily seance. A large sized electrode covered with amadou or chamois, made to conform to the shape of the calvarium, should be placed with the positive pole over the frontal region, and the negative electrode of the same size at the nucha. A tonic and alterative effect is produced by cerebral galvanism, improving the circulation and nutrition of the meninges and adjacent tissues.

The forced following of new lines of thought and forced action of the torpid brain stimulates the circulation and aids in elimination from the brain, as contraction of a muscle hastens tissue change of its substance. In the moderate elevation of temperature as found in exacerbations of this chronic state under treatment, saline laxatives, increased quantity of drinking water, lithia water and digitalis should be used. A cold water coil to the head or a cold head bath gives marked relief. Frequently a leg pack lasting an hour, or a hot bath of sufficient duration to dilate the cutaneous capillaries, with cold to the head at the same time, gives rapid results. The cases that follow were treated on the above principles:

Case 1.—Mr. O., male, aged 36; no history of specific infection but possible exposure ten years previously. Remained apparently well for seven years, and in April, 1891, had slight paralytic stroke affecting left side. Was abed three weeks and gradually nearly recovered use of left hand and leg. Again went about business, though mentally not so acute as formerly. In September, 1895, began to have grand ideas about himself, his business and other people. He quit business on his own account and went to visit relatives, thinking rest and change would restore him. On examination, found thickened hesitating speech with difficult articulation, unequal pupils; central paresis, lower facial nerve left side, no other branches. Patient could not read, from lack of concentration, nor write intelligently. Was headstrong, irritable, and suspicious. Had lost weight and was eating and sleeping poorly. There was active treatment after diagnosis of chronic meningitis; gained twenty-two pounds and improved in every way. Returned home but failed to continue medicine. Returned last May, and for three weeks, on resumption of treatment, improved somewhat slowly; afterward, began to lose use of sphincters; fell into semistupor and hebetude; acknowledged he had specific disease thirteen years before but concealed it. At the end of the sixth week he died.

Autopsy.—General cerebral meningeal thickening; no indication of fresh inflammatory action. Cranial nerves normal. Chronic endarteritis, anterior and middle cerebral vessels not complete: no occlusion nor thrombosis; no aneurysms nor hemorrhage; no gross macroscopic lesion of brain substance. No microscopic sections made.

Case 2.—Age 36; married. Good family history. Previous history of patient good. In 1886 had urethral stricture but disclaimed any infection. In 1891 acknowledges exposure to specific infection. Was treated three months homeopathically. Secondary symptoms not severe, and he attended to business until two years ago. He then complained of sharp shooting pains in left temporal region and whole side of the head. This continued for six months and was followed by hemiplegia on right side of the body, from which he recovered. The pain and headache then shifted to the right side of the head. This was followed later by numbness of the left extremities and formication of the entire left side of the body.

The headaches, which were of an explosive type, were so severe that they were only relieved by morphin hypodermically at regular intervals, being always worse at night and preventing sleep.

The patient was irritable, restless and nervous with general mental aberration. Appetite and digestion fairly good. After eighteen months continuous treatment on the above lines the patient recovered.

ANESTHESIA OF THE TRUNK IN LOCOMOTOR ATAXIA.

Presented to the Section on Neurology and Medical Jurisprudence at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY CHARLES W. BURR, M.D.

PHILADELPHIA, PA.

Hitzig¹, Lähr² and Patrick³ have described as a very frequent symptom in locomotor ataxia, a condition of tactile anesthesia occurring in the trunk, usually symmetrically situated on the two halves of the body, most frequent at the level of the nipples, and not bounded by the distribution of nerve trunks, but corresponding to the spinal roots or their intramedullary fibers. A series of ten cases recently examined by me agrees more or less with the conclusions drawn by these observers. In some, however, the condition found was different. I will not give the histories of the cases but ask you to accept my diagnoses. I will say, however, that none were recent, all being of some years' standing, all having quite marked ataxia, and none being paralytic. In the first case there was a band about three inches wide extending around the trunk at the level of the nipple in which though tactile and pain sense were well preserved there was marked confusion in the temperature sense, the usual defect being that he mistook cold for heat. In a second case there was no real tactile anesthesia but a partial analgesia, an inability to distinguish between touch and slight pain over an area about three inches wide on the chest in front of the level of the axilla and passing down on the inner side of the right arm to the elbow, and of the left arm to its middle third. Posteriorly, there was only a small area over the spine at a corresponding point, in which there was analgesia. At the level of the floating ribs on either side behind, was another small band of analgesia, and finally, in the left popliteal space a patch. There were no other sensory defects over the entire body.

In a third case there was a band of tactile anesthesia around the entire trunk and reaching from the umbilicus to the nipples. Within this area in front was a small irregularly rectangular area of total anesthesia.

In a fourth, there was a similar broad band from umbilicus to nipple and extending around the entire body, but there was also confusion of hot and cold and some analgesia, and a pin prick always felt warm.

A fifth case was typical, that is, involved touch

alone, but the upper and lower boundaries on the two ribs did not exactly correspond.

In the sixth, there was not absolute tactile anesthesia, but from the nipple to the axilla and extending around the trunk and down the inner side of either arm, there was an area in which tactile sensation was much delayed. There was also delayed sensation on the outer side of the entire left leg and the right calf.

In the seventh, there was a longitudinal, rectangular band about two inches wide over the entire thoracic spine, in which there was tactile anesthesia. On the front of the chest there was a small area over each great pectoral at the level of the axilla, and on the left side extending down the inner aspect of the arm to the elbow.

The eighth case revealed in different parts of the body almost all possible sensory defects. The left lower leg was completely anesthetic in front except the toes. On the right tibia was a large irregular area of total anesthesia. The forearms and hands were normal. Over the chest and from two inches below the nipple to above the lower border of the axilla and down the anterior aspect of both arms to the elbows there was tactile anesthesia. There was also tactile anesthesia over the anterior aspect of the right thigh. On the trunk temperature sense was normal, but in the legs even when not anesthetic there was confusion of hot and cold.

In the ninth case there was no tactile anesthesia on the trunk.

It must be accepted as proven that there occurs in locomotor ataxia such an anesthesia as Hitzig, Lähr and Patrick have described. I think, however, that it is not quite so frequent as their figures indicate, though my series of cases is far too few to draw conclusions from. How early in the disease it may develop is as yet unknown, but it may be present uncomplicated by other sensory defects very late. It may occur without sensory defects in other parts of the body. Its distribution, as Lähr says, corresponds not to the distribution of the peripheral nerves, but to that of the spinal roots or their intramedullary fibers, in which respect it simulates disturbances of sensibility following lesions of the spinal cord and the posterior roots. It is probably not characteristic of locomotor ataxia, but may occur in any local spinal meningitis. Fortunately its little use as a diagnostic feature does not greatly matter since locomotor ataxia is so unlike other diseases in which it may occur. It is of value in studying the natural history of the disease.

DISCUSSION.

DR. HUGH T. PATRICK—I found the pain sense lost while the tactile sense was retained in a case of syringo-myelia examined not long ago. I think there can be no doubt about the diagnosis of syringo-myelia, although in the absence of a postmortem one would hesitate to be positive. In this case there was the trunk anesthesia extending along the inner surface of the arms, which has been described as typical of locomotor ataxia, with the exception that the loss of pain sense is in a zone considerably wider than the loss of tactile sense.

One of my reported cases of well developed tabes in which there was no trunk anesthesia, a case examined about a year ago, I have just learned has developed a well marked trunk anesthesia of this typical kind. I have since seen the same thing in other cases; indeed, in my first paper I mentioned that it had been found in other diseases and would probably be found in syringo-myelia. I saw this recently in a case which I think is not tabes but some acute lesion of the cord, and also very well developed in a case which I think was acute lateral sclerosis of the cord.

DR. C. C. HERSMAN—I have found tactile anesthesia, or analgesia, a number of times, especially in specific cases. Since

¹ Ueber traumatische Tabes und die Pathogenie der Tabes im allgemein, Berlin, 1894.

² Archiv für Psychiatrie, Vol. xvii.

³ New York Medical Journal, Feb. 6, 1897.

Gowers has placed the specific cases at 80 per cent. and only accounts for 10 per cent. of idiopathic, possibly we can say locomotor ataxia without specifying the pathology.

I have a case of specific trouble in which this analgesia is present. The patient has tactile sense but loss of feeling in patches.

Dr. HAROLD N. MOYER—Since the publication of the papers referred to I have examined seven cases and the symptoms were present in all. These are the only cases I have examined, with the exception of two children, one a very marked ataxic; both cases of Friedreich's disease; neither of these children has any of the zones of analgesia or anesthesia. I have observed it, however, in one case of well marked syphilis in the spinal cord, which would not be pronounced in any way an ordinary case of tabes; it was upon one side, and corresponded to a very marked parietic condition on that side.

Dr. CHARLES W. BURR of Philadelphia—I have recently examined two cases of Friedreich's ataxia, and there was no such trunk anesthesia present.

THE USE AND ABUSE OF ELECTRICITY IN THE TREATMENT OF THE SO-CALLED NEUROSES.

Presented to the Section on Neurology and Medical Jurisprudence at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY L. HARRISON METTLER, A.M., M.D.

CHICAGO, ILL.

Of all the therapeutic measures employed to combat disease, electricity is probably the most abused. This is due partly to ignorance, partly to indifference. The extreme diversity of opinion in regard to it as an agent for good is ample testimony of the widespread ignorance concerning its powers. It is a fact that electricity is beneficial in the treatment of disease or it is not; it can not possess two dissimilar qualities at one and the same time. It is absolutely inconceivable that electricity should be at once perfectly neutral and most curative under similar conditions. Therefore, the differences of opinion held in regard to it can not be attributed to anything in the agent itself. The differences of opinion, must have their source in those who use the agent. The users themselves must differ either in their knowledge or in their methods of handling it. These assertions, I admit, are trite, but if their truth can be brought home to those who attempt to employ electricity, something may be gained in the way of more extensive positive knowledge and greater uniformity of opinion.

When one operator insists that all strictures can be reduced by electricity, and another says no strictures can be so affected, surely the electricity can not be at fault for that is presumably the same in both hands. The discrepancy lies with the operators. When Möbius of Berlin argues that the only positive effect of electricity upon a patient is of a mental, suggestive or psychic sort, and Apostoli of Paris teaches that solid fibromata may be made to vanish under the solvent action of the electric current, it is time for us to enquire wherein the methods and personal characteristics of Möbius and Apostoli differ; for, presumably, they have both used the same electric current—the only electricity known in this world—upon the same sort of pathologic conditions, and under corresponding circumstances. The question therefore becomes largely one of personal honesty and relative powers of interpretation. Many things appear different to different men, but if electricity produces certain physiologic phenomena, such as muscular contraction, catalysis, cataphoresis and modification of local temperature, it is incomprehensible

that these obvious phenomena should not be seen by optimist and pessimist alike. Surely, if muscles do really contract under electric stimulation, the patient as well as the operator can not honestly declare that such contraction is a sort of mental aberration or psychic hallucination. If chemic changes are really wrought in the fluids of the body by the poles of a battery, certainly the fact must be something more than a mere figment of the imagination.

It is universally admitted that electricity does produce certain manifestations in the normal tissues, these manifestations always being the same under the same conditions. I enumerate some of those physiologic actions upon which experimenters are pretty well in accord. They are to be noted as dynamic, electrotonic, thermic, electrolytic, catalytic and cataphoric. There are other effects less constant, and some, as Erb says, "that we may not now have even a suspicion of," but those I have mentioned are constant and apparent. As a mechanical irritant and as a chemic solvent, electricity has undoubted force. Certain details and minutiae in the manifestations of this force may at the present time be open to controversy, but that the electric current is not absolutely inert in its effect upon the body is admitted. It certainly does influence nerve currents, however that influence may be explained. Its electrotonic force diminishes or increases the transmission of sensory and motor impulses along the respective nerves, according to the ascending or descending direction of the electric current. Muscles do most obviously contract, whether the pole of the battery be applied directly to the muscular tissue or to the related nerves, and Pflüger's famous law in regard to these contractions is a positive scientific fact. Local anemia and hyperemia are, beyond dispute, caused by the action of the electric current. Chemic, mechanical and physiologic effects are most clearly discernible in the skin, as a result of the application of the galvanic current. The same may be said of its action upon the blood.

In addition to these particular activities, there is a whole series of manifestations produced by the dynamic effect of the direct application of the electric current to the brain, the spinal cord, the sympathetic nerves, and nerves of special sense, the sensory and motor nerves, the voluntary and involuntary muscles and the various glands and organs.

The functions and products of the secretory glands are modified by the irritative action of the electric current, sometimes being increased and sometimes diminished according to the kind and quantity of electricity used. Simple observation shows that the blood is affected by the current and that clots are formed while hydrogen and oxygen as well as acids and alkalies are evolved at one or the other electric needle immersed in the blood stream. The local effects upon nutrition are apparent enough to any unprejudiced observer and are to be noted as mechanical, physio-chemic and physiologic.

It is not my desire to refer more minutely to the great subject of electro-physiology. I wish merely to emphasize the fact that there are electro-physiologic phenomena, and to consider how these effects are to be utilized in the treatment of a special class of diseases.

Why is electricity as a therapeutic measure so misused? Many reasons might be suggested, but most of them would come under the head of ignorance or indifference. The expense of a complete electric out-

fit and the trouble of applying the agent are two important hindrances to its universal adoption. It is easier and less expensive to write a prescription than to give an electric treatment. To tell a patient to purchase a "family" battery and to hold the electrodes in the hands while "the current is flowing," is about as sensible as to tell him to go to a drug store and take "some" strychnin as strychnin is a good "nerve tonic." Not to know when and how to employ the galvanic instead of the faradic current, reveals about as much knowledge of electro-therapeutics as not to know when and how to administer belladonna. Far too many practitioners do not distinguish between the various currents, galvanic, faradic and static, in their applications. It is all electricity, they loosely argue, and if the patient is not benefited by the form of electricity which has been administered, they conclude the agent is of no value. Again, they do not measure the dosage of the electricity given, but too often depend upon the feelings of the patient. In some varieties of disease the electric current works deleteriously if it is so strong as to cause the patient to be conscious of it. It is a mystery, therefore, how in such cases the electricity is to be administered with any sort of intelligence, if no measure of the dosage is employed. I have occasionally known the practitioner to first try the current upon himself and depend upon his own sensibility as a guide to the administration of the agent to the patient. One might as well exhibit quinin or opium to oneself with no thought of human idiosyncracies or differences of constitution as a guide for the exhibition of the drug to the patient.

Human nature is full of prejudices and more than once have the slower results obtained by electricity in certain cases been frowned on because of the more brilliant and rapid effects produced by surgery. All prejudice aside, however, it is a fact that in many of the neurotic affections—especially the neuroses—electricity is the curative agent *par excellence*, and while there is less *éclat* associated with it than with a surgical operation, it accomplishes its results without mutilation. So careful and conservative a clinician as Erb of Heidelberg says that "electricity is an extremely powerful and many-sided remedy and that more evident and undoubted curative effects may be attributed to it in diseases of the nervous system than to almost any other remedy. I am not guilty of exaggeration when I say that the curative effects not infrequently astonish even the experienced physician by their magic rapidity and completeness."

And yet there are grave difficulties encountered sometimes in the treatment of these diseases with electricity. They are largely, however, diagnostic and pathologic. Everyone admits that, physiologically, electricity stimulates nutrition. Naturally it follows that in those troubles in which diminished nutrition is the principal factor, electricity should play an important rôle therapeutically. Here is where much of the differences of opinion in regard to the value of electricity have their origin. What are the nutritional diseases and how can they always be accurately diagnosed?

Again, it is recognized that physiologically, electricity manifests a certain amount of catalytic power. Most rational would it seem, therefore, to employ this agent in the treatment of those conditions, like tumors, in which a dissolution of the tissues and fluids is desirable. But who will always and positively tell

what conditions are amenable to this solvent force? Obviously we have many things to learn, and it is undeniable that electricity, like a host of other therapeutic agents, must to a large extent be used empirically. It behooves us not to condemn a measure which empirically is shown to be beneficial merely because we do not fully understand the pathology of the diseases in which its grand effects are so apparent.

A neurosis or functional disease is one of the enigmas of medical science. All that we can say is that the tissues and organs involved are functionally perverted, which is nearly equivalent to saying nothing. Many of the so-called functional troubles are purely reflex in character. Sometimes we can discover the distant organic lesion that is the prime cause of the reflex disturbance; more often, however, this final cause remains undiscovered or is found only after the patient has been subjected to a number of mutilating surgical operations. And in very many cases the functional trouble remains after all supposed organic lesions have been removed. Who has not seen cases in which ablation of the ovaries for epilepsy or insanity has failed to accomplish the desired result? Not always does a circumcision put a stop to a chorea or the fitting of a pair of glasses remove a headache. It is well that these operative procedures should be done when needed to clear up strong presumptive evidence that the organic lesions are the source of the neurotic troubles. Other measures, however, should always be given a thorough trial before any such radical methods are instituted. The ultra-mechanical treatment of such conditions as dysmenorrhea, neuralgia, vaginismus, epilepsy, seminal incontinence, intestinal constriction, etc., is not always successful even when most radically undertaken. To argue that an operation is always radical is no argument against trying other measures first. Radicalism is not always effective and too often transcends the limits of what is judicious and necessary. There are men who propose the production of abortion as a radical cure for severe vomiting of pregnancy. By the same process of reasoning these men would probably declare for amputation of an arm for a painful neuroma. Medicine should conserve as much as possible, and for that reason heroic measures should always be approached gradually and only as a last resort. Since therapeutics is only a means to an end and not the end itself, the harsher the means the more reluctantly they should be adopted. If a neuralgia can by any possibility be alleviated by electricity, no argument on the ground of radicalism can console a patient for a surgical mutilation.

There is a large class of neuroses in which the cause of the trouble seems to be inherent in the tissues themselves. The best explanation we can offer of their pathology is that they are the result of impaired nutrition. The chemic or molecular state of the nerve cells is in some way at fault. Perchance this is brought about by a local vasomotor irregularity or by some inherent defect in the metabolic functions of the cells themselves. If the circulation is not what it ought to be, the pabulum carried by the blood to the nervous structures will be deficient or in excess, and these structures will be starved or over-nourished. On the other hand, if the cells themselves are wanting in tone so that the pabulum is not normally assimilated and metamorphosed into their own chemic or molecular condition, these structures will not functionate as they should, but give rise to a so-

called functional disease. There may be, and in some instances undoubtedly are, irritants and toxins in the blood that exert a deleterious influence upon the delicate nerve cells so as to modify their functional activities. Many cases of chorea are due to the uric acid diathesis, while not a few mental symptoms are believed to be caused by a toxic condition of the blood. Even in these cases, however, the essential trouble in the histologic structures is largely nutritional, whatever the nature of the prime cause may be. All this class of cases, the so-called neuroses, are therefore especially amenable to electric treatment. Hysteria, insomnia, spinal irritation and nervous exhaustion are always immensely benefited by the electric treatment when it is properly administered. When I see, as I have in many of these cases, an improvement in every symptom, an increase of body weight, a reawakening of the appetite and a more natural performance of all the bodily functions, I am at a loss to understand how such results can be attributed solely to the mental impression or psychic influence excited by the electric current. I can as easily believe that a brick wall may be raised by the practice of hypnotism upon it by the master mason as to believe that such physical manifestations as restored digestion, circulation and restored functions of all sorts in a neurasthenic are the result of a kind of electro-hypnotic influence. I would have to convince myself that electricity does not really stimulate, does not irritate, that in fact it is physically absolutely neutral in its effects, local and general, while the patient's mind alone brings about all the wonderful changes in the activities and appearances of the bodily tissues. No, the psychic theory in regard to the power of the electric current is not only irrational and illogical, but it is emphatically opposed to most observable and tangible facts. I am not over-enthusiastic when I say that in the treatment of the neuroses electricity is the sovereign remedy. In selected cases it accomplishes most favorable results, as I could easily show from my case-book. Whether the influence of the electric current upon the nutrition be the sole explanation of its *modus operandi* or whether in addition to its electrotonic, catalytic and cataphoric properties, it possesses other more subtle powers, is a matter of small consequence in discussing the reality of its effects in the treatment of the neuroses. Because it is so powerful an agent is the very reason why it provokes such a diversity of opinions. Electricity is not a panacea even in the treatment of the neuroses, its most favorable field. In accordance with our present knowledge only that class of cases in which nutrition is primarily at fault call for it. As I have already indicated, certain neuroses are mere reflex manifestations and while electricity may benefit them for a time, it can not be expected to produce a cure until the original cause of the reflex is removed.

A young woman was recently referred to me who had been treated for three months by a gynecologist, on the theory that her neurotic symptoms, which were most distressing, might be due to some pelvic disease. Showing no improvement as a result of the local treatment, she took electricity, baths, massage, etc., and persisted in the general treatment greatly to her benefit. She was an orphan, of a naturally sensitive nature, overwhelmed with financial troubles in connection with her estate, and uncertain as to the future of her life. All these factors had combined to institute a train of neurotic manifestations such as insom-

nia, restlessness, irritability, loss of appetite, nervous dyspepsia, weakness of memory, want of the power of concentration, fugitive pains, backache, etc. Examination of the pelvic organs, by myself as well as by others, discovered no pelvic trouble whatever. I was surprised that the simple history of this case did not have more influence in the diagnosis made by the gynecologist, but when I found no disease whatever of the pelvic organs, I naturally had my suspicions in regard to the honesty or ability of her attendant. Another case sent to me was that of a young woman who had received much electric and anti-hysteria treatment near her home, without apparent benefit. She was herself to blame in this instance, in having been unwilling to submit to a vaginal examination. This examination, made by myself and by another, on account of her persistent backache, leucorrhea and dysmenorrhea all coming on shortly after a severe fall, revealed a pronounced retroflexion of the uterus with chronic endometritis. In such a case electricity was naturally without benefit to the neurotic condition except temporarily. Three months' treatment here for the pelvic trouble sent the girl home well, happy and grateful.

I have related these two well marked contrasting cases to illustrate the use and abuse of electricity. I could give others, even more in detail but mere repetitions consume time without adding information. A correct diagnosis is an absolute *sine qua non* in the proper administration of electricity. Too often, however, it seems that with some practitioners the more obscure the diagnosis is, the greater the need for electric treatment. If a paralysis or a neuralgia, for instance, can not be assigned to a definite cause, then as a last resort electricity is tried. I think I am not far out of the way in saying that when a set of neurotic symptoms remains unrelieved by the application of the electric current, the practitioner, to be honest to himself and to his patient, should conclude that his diagnosis is wrong and that his therapeutics is being misapplied. The supposed neurosis is in all probability a reflex of some sort, and calls for other treatment than the electric. More than once have I had headache cases come to me in the hope of being benefited by electricity, while a most superficial examination indicated some form of eye strain. I must frankly state, however, that I have had not a few cases which had been fitted with glasses, return to me with no modification of the old headache, until a more thorough course of general and electric treatment had been instituted. Neurologists are acquainted with such a condition as pain habit, and in lieu of a better explanation I find I have to attribute some of these pains to such a habit.

In the electrical treatment of the neuroses, I find that a combination of galvanism and faradism gives the happiest results. I use a galvano-faradic apparatus. In galvanization of the spine and general muscular faradization, I have the patient remove all clothing and lie on a couch, without exposure, under a large sheet. Sponge electrodes about five inches in diameter, having convenient handles attached are used. At first, with the small, ordinary hand electrodes, one at the nape of the neck, the other over the sacrum or epigastric region, the spine and sympathetic system of nerves are galvanized for four or five minutes. The feeblest possible current is used, the strength never being greater than is just sufficient to cause a slight metallic taste in the mouth. By measurement

it should not be more than from five to fifteen milliamperes. At this stage of the treatment the patient usually declares that he feels a decided local warmth at the negative pole. While maintaining the electrodes in their respective positions, the current is reversed some five or six times with the current reverser of the battery.

With the larger sponge electrodes general faradism is applied to every part of the body. One pole is placed at the nape of the neck or under the sacrum, while the other is passed successively over all the muscles causing in them a gentle but decided contraction. Many patients are over-sensitive, and in such it is advantageous for the physician to hold one pole of the battery in his left hand while he uses his right hand to administer the electricity with a gentle massage to the patient. This is more tiresome to the physician, and fortunately is necessary in only a small percentage of cases. I have used the method many times without feeling any bad effects from the electricity passing through myself. The advantages are that the physician can control the strength of the current better and a sensitive, nervous patient is not annoyed by any sudden shocks. While the spinal galvanism should not be prolonged beyond five minutes, as a rule, the general faradism is gradually increased in strength and time until the latter is an hour and the former produces almost painful contractions of the muscles.

In selected cases this simple method of administering electricity affords, after a few seances, a grateful feeling of rest, sleepiness and well being, which continues until in the end the whole constitution partakes of the improvement, and the patient looks and feels once more like a normal being. If after the first two or three applications a restful feeling and a desire for sleep are not experienced, the physician's suspicions should be awakened. If a condition of over-excitability is produced he may be quite certain that his diagnosis is wrong, and the case is one not amenable to electric treatment.

With a proper knowledge of the qualities of the electric current, with more care in the making of the diagnoses and the selection of cases, and with an intelligent scientific application of the agent, electricity, in the treatment of the neuroses ought not to be abused as much as it is, but it ought to be used with a degree of success that will award it its due place among our therapeutic resources as one of the most powerful and effective in the conflict with disease.

4544 Lake Ave.

A CASE OF LOSS OF BLOOD FROM THE RECTUM DUE TO MUCO-MEMBRANOUS ENTERO-COLITIS, AND TWO OF LEUKEMIA.

Clinic delivered at the Jefferson Medical College Hospital.

BY H. A. HARE, M.D.

Professor of Therapeutics and Materia Medica, Jefferson Medical College of Philadelphia.

PHILADELPHIA, PA.

The first patient is a man of 23 who is somewhat thin and anemic, and whose face shows the signs of mental depression and lack of nervous energy. His history is, that he was in perfect health until about two years ago, when he was suddenly seized with a severe hemorrhage from the bowels, the blood being quite bright in color. He tells us, however, that he

has had no diarrhea at any time, but on the contrary suffers from obstinate constipation. There is nothing in his history which points clearly to the cause of these bloody movements, which have continued from time to time, generally once or twice a week ever since he was first taken ill. The frequent loss of blood has resulted in general debility and anemia. He tells us that an examination of his passages not only reveals blood but a large amount of mucus which appears in shreds or stringy masses. He often has much griping pain and flatulent distension, his appetite is variable and his diet is an irregular one because he is afraid to eat certain articles lest they produce an increase in his discomfort. Every few days he is seized with an attack of looseness of the bowels which seems as if it were an effort upon the part of the bowel to get rid of an excessive quantity of mucus and feces which have accumulated. His urine is normal.

When a case of hemorrhage from the bowels comes before you, the possibility of it arising from a number of different causes at once enters your mind. First, it is possible and most probable in such a case that the hemorrhages come from hemorrhoids, but the man tells us that he has no sign of any congestion of his hemorrhoidal veins. This does not, however, prove positively that the blood has not this origin, for the most severe cases of bleeding from the rectum are seen in those persons who have no large dilatations of the hemorrhoidal veins, but in their place have small arterial twigs in a dilated and hyperemic state and these little bunches of vessels containing arterial blood, when scraped or eroded by fecal matter give free vent to little arterial spurtings. A careless examination of the rectum might result in their being overlooked, but a careful examination with a speculum will often reveal their presence.

Relief may be obtained by touching them very lightly with the tip of a fine glass rod dipped in nitric acid, the resulting scar puckering the blood vessels and preventing further hemorrhage, or in other cases an application of nitrate of silver or of dilute nitric acid for its astringent effect does equally well. I have had this young man carefully examined, however, and the report is that there is no sign of such bleeding points and we have therefore to look further for the cause of his trouble. Is it possible that the blood arises from a duodenal ulcer? I think not; for first, duodenal ulcer is a rather rare condition, and second, the blood which comes from such an ulcer is nearly always dark and tarry, through the action of the digestive juices of the bowel upon it, whereas the blood this man passes, he tells us, is quite bright and arterial in hue. Then, too, he has no pain in the neighborhood of the duodenum; such as is usually felt when ulcer of this portion of the alimentary canal is present and, finally, the blood is not well mixed with the fecal matter, but is well separated from it in the movements, although if it arose in the small intestine we would expect it to be thoroughly mixed with the stools. On the other hand, duodenal ulcer is far more frequent in males than in females. I think for the reasons given we may exclude the possibility of the blood arising from an ulcer in the duodenum.

The next cause to be thought of is cirrhosis of the liver. This condition, as is shown so well in the illustration of the results of cirrhosis of the liver in my book on "Diagnosis," results quite frequently in grave engorgement of the various abdominal viscera,

so that we frequently have hemorrhages from the stomach as the result of the enlargement of the gastric and esophageal veins and of the chronic catarrhal condition which results. Similarly it might be possible to have bloody movements from this cause as the result of the interference of the abdominal circulation and particularly from congestion of the hemorrhoidal plexus, but he has no history pointing to that most frequent cause of cirrhosis, alcoholism, nor does physical examination reveal any signs of this slow pathologic process in the liver. I think we may, therefore, exclude the possibility of the cause of his hemorrhages being hepatic cirrhosis. That he is not suffering from hemorrhages arising from old ulcers remaining after typhoid fever is proved by the fact that he has no history of this disease. He is, however, a markedly neurotic patient and the fact that he has these peculiar stringy movements, that he suffers from constipation with marked intestinal discomfort and with occasional attacks of diarrhea and from various spots of tenderness in the abdomen, which are not constant, leads me to conclude that he is suffering from ordinary muco-membranous entero-colitis. In some of these cases actual membrane seems to be passed from the bowel, but in the majority of them thick, tenacious strings of white mucus are passed with each movement. The proper treatment for this man is to institute, as closely as possible, what is known as the rest-cure treatment, which by improving the conditions of his nervous system, will indirectly cure this condition. His constipation must be overcome by the use of proper laxatives, such as cascara sagrada, to which may be added small quantities of lobelia to increase intestinal secretion, or if he has an attack of diarrhea this must be controlled by proper remedies. He must have a nourishing diet, which should be, however, free from potatoes, beans and similar articles which cause fermentation and the development of large quantities of wind in the bowel. Milk should be given him very cautiously until we are sure that he can digest it. In addition to this treatment his digestion should be aided by bitter tonics, by the use of pancreatin or pepsin, and, almost as important is the rest-cure. He should receive high injections of as hot water as he can bear, in each two liters of which there should be placed about 1.3 grams of the sulphocarbonate of zinc. Should no diarrhea be present we may place in the hot water from 2 to 4 grams of boric acid. His buttocks should be elevated before the injection is given, the fountain syringe should not be raised more than eighteen inches or two feet above the bowel, in order that the water will enter the bowel very slowly, and this treatment should be given at first every night and afterward at least three times a week. During the periods of his constipation gentle massage of the abdominal area may be carried out with great advantage, but it will have to be most gentle, particularly when it is first employed.

The other two cases are very much more important; they represent that not very common condition known as leukemia, or as it was formerly called, leucocythemia. In an earlier clinic I showed cases representing ordinary anemia, chlorosis and pernicious anemia, in all of which conditions the variations in the blood depended chiefly upon alterations in the character or number of the red blood corpuscles. These cases, however, represent but little change, comparatively speaking, in the red corpuscles, and very marked change in what are known as the white corpuscles or leucocytes.

The white blood corpuscles appear in several forms: first, we have the small white blood corpuscle, scarcely as large as the ordinary red corpuscle, which is called a lymphocyte; this has a very large nucleus, which so completely fills the body of the corpuscle that there is no free protoplasm to be seen around its margin. Next we have what is known as the large mononuclear leucocyte, a corpuscle considerably larger than the red corpuscle containing a large single nucleus which is surrounded by an area of transparent protoplasm. Next we have a white corpuscle known as a transitional leucocyte, in which the nucleus of the large mononuclear leucocyte looks as though it were undergoing some transitional change in its shape and character. This corpuscle is not, however, exceedingly important in diagnosis. Then we have what is known as the polymorphous or polynuclear leucocyte, a white blood cell which, as its name indicates, contains either several nuclei or a nucleus of very irregular shape (polymorphous). This corpuscle contains in its protoplasm a number of fine granules which take certain neutral stains and are therefore known as neutrophiles. In addition we find in normal blood another white blood corpuscle, generally polynuclear in character, in the protoplasm of which may be found large granules, much larger than those just described, which readily take an acid stain such as eosin. They are called eosinophiles. At one time the presence of those cells was considered of importance in the diagnosis of leukemia, but they are now considered not so important. These, then, are the white corpuscles which are found in normal blood. What are the changes which we find in leukemia? Before I describe them I must recall to your mind that we have two forms of leukemia; first, spleno-medullary leukemia, which is by far the most frequent type. In this disease we have great enlargement of the spleen and liver and marked pathologic changes in the medulla of the bones and, as a result of these changes, it is supposed that we have developed an excessive number of large mononuclear leucocytes, and at the same time another white corpuscle not found in normal blood is seen which appears as a myelocyte, a corpuscle of very large size with a very large staining nucleus, usually situated toward one side of the cell and in the protoplasm of this corpuscle are to be found numerous fine granules. The presence of these two corpuscles and the mononuclear cells in excess and the development of the myelocytes affords us strong evidence of the presence of spleno-medullary leukemia, particularly if we find in association with these signs the dyspnea of anemia, the pallor, retinal hemorrhages, possibly hematuria and the marked enlargement of the spleen which are so characteristic. The older of these two patients presents just these signs and symptoms. An additional sign of leukemia may be, perhaps, considered in the marked decrease in polynuclear leucocytes which are present, and this enables us to separate leukemia from other cases in which we simply have excessive leucocytosis, because the polynuclear leucocytes are those which are increased in excessive leucocytosis but decreased in leukemia. Repeated examinations of this man's blood show the following changes: September 30 he had 2,458,000 red corpuscles, 28 per cent. of hemoglobin and 368,750 white cells, the proportion of white to red being 1 to 6. Two months later under ascending doses of arsenic his hemoglobin had risen to 50 per cent., his red corpuscles, however, numbered only 2,048,000, but

the white corpuscles had been decreased to 93,750, or 1 to 23.

Today his hemoglobin equals 63 per cent., his red corpuscles 4,000,000 and his leucocytes only 19,000. The proportion therefore is 1 to 210, which approximates the normal proportion very much more closely than the earlier count. The blood also shows that the myelocytes are present in the proportion of from 8 to 13 per cent., and it is a noteworthy fact that his polynuclear leucocytes, which are usually decreased in this disease, amount to from 51 to 66 per cent., which is about the number usually found in normal blood. His spleen is found to be greatly enlarged. It extends almost to the anterior superior spine of the ilium and in the middle line as far as the umbilicus, but his color has greatly improved and there are many men who would appear far more anemic than he, although they would consider themselves as being in perfect health.

The second case is far more interesting because much more rare, representing as it does a case of possible lymphatic leukemia. It is that of a young man of 23, a barber by occupation, who is intensely pale and yellow looking. An examination of his chest and arteries shows loud anemic murmurs, his spleen is enlarged to even greater extent than the patient first brought before you and we have records of his blood over many months. October, 1895, an examination of his blood showed that his hemoglobin was 30 per cent., his red blood corpuscles 2,060,000 and his leucocytes 8000. He has been in hospital off and on since that time and we have a great many counts of his blood. His case is not a typical one, but I think we can say that it is one of lymphatic leukemia. At the present time his hemoglobin is 33 per cent., his red corpuscles the same as before and the leucocytes 6200. While the red corpuscles are somewhat decreased, as they frequently are in leukemia, the white blood corpuscles are not increased as is usual; indeed, this proportion between white and red is often seen in health. It is only when we consider his various corpuscles that we have much light thrown upon the diagnosis. We then find that his lymphocytes, which are ordinarily present in comparatively small numbers, amount to 84 per cent., that polynuclear leucocytes, which usually make up a large proportion of the white cells, only amount in this patient to 8 per cent., while the mononuclear leucocytes amount to 4 per cent. There is also absent in his case one other frequent sign of lymphatic leukemia, namely, very great enlargement of the lymphatic glands all over the body. This boy has no such enlargement, but his lymphocytosis, combined with his profound anemia, the fact that he has had hematuria, that he has hemorrhages in his retina and that he is intensely anemic and pallid without a corresponding loss of flesh, seem to make the diagnosis fairly clear.

In many of these cases of leukemia we find in addition to a decrease in the number of red corpuscles, an abnormal red blood corpuscle which possesses a nucleus, this corpuscle being called a normoblast and sometimes also possessing ameboid movement. In the presence of a patient suffering from multiple enlargement of the lymphatic glands, a symptom which this boy might present, it would be incorrect for you to jump to the conclusion that he was suffering from lymphatic leukemia, because a similar enlargement is seen in what is known as Hodgkin's disease or pseudo-leukemia and multiple tubercular infection.

The treatment given these patients has been a

nourishing diet, the meeting of current symptoms which have seemed of most importance, and ascending doses of arsenic until they reached the physiologic limit of the drug.

FIVE CASES OF CHOLELITHIASIS.

BY BAYARD HOLMES, M.D.,

PROFESSOR OF SURGERY IN THE COLLEGE OF PHYSICIANS AND SURGEONS OF CHICAGO, THE MEDICAL SCHOOL OF THE UNIVERSITY OF ILLINOIS.

The following cases are reported because each of them contains at least one point of real surgical interest:

Case 1.—Indistinct pain in the abdomen, with sick headache; the morphin habit; empyema of the gall bladder; cholecystostomy; recovery. The patient was a physician, 45 years of age, who came to Dr. Waugh's sanatorium for the treatment of the morphin habit. He was of very regular habits, used no tobacco or alcohol and had no significant previous history. He had indistinct pain in his back and abdomen for several years and was accustomed to take small doses of morphin to relieve this distress. These doses increased, however, in frequency and size until he found himself, under one pretext or another, taking larger and larger doses, up to 0.45 or 0.52 grams a day. He was bright and had been able to follow his practice, which was large and diversified. On coming to the sanatorium he stood the treatment well for a week or two, when without apparent cause and without any very great increase in this indistinct pain in his back he gradually began to have an evening rise of temperature, with some sweat. At length symptoms of peritonitis, distension of the abdomen and tympanites appeared, and it was discovered that his right abdominal region was filled by a tumor six inches long and three or four inches wide. It was so large a tumor that it was at first looked upon as a peri-appendicular abscess. In the course of twenty-four hours the symptoms were so grave that I was called in to open the abscess. This was Dec. 16, 1893. The patient at this time was only partially conscious; his abdomen was slightly tympanitic; the bowels had been freely moved by an enema; the patient's temperature was 102, his pulse 120. He had never had any paroxysmal pain, but complained of a deep pain in the back, which was relieved by the use of morphin. In examining the eyes the pupils did not show the effect of the morphin; the tongue was coated typhoid-like; the lips dry and parched; the skin hot and dry; the respirations rapid and superficial, as in peritonitis; the heart's action was perfect, but rapid; the abdomen was slightly distended, and in the right side was found a tumor, round, smooth and pressing up against the abdominal wall, which tumor I readily recognized as a greatly distended gall-bladder or possibly a pyonephritic tumor. His urine was examined and found to contain a trace of albumin and was otherwise highly concentrated. He urinated voluntarily. The case was considered one of great gravity, and an immediate operation was undertaken. The abdomen was opened by an incision along the outer border of the right rectus muscle two and one-half inches long. The tumor showed itself in the wound unattached to the viscera. The first effort, however, to examine it resulted in rupture of the sac and the discharge of a large quantity of thick pus. The walls of the tumor were instantly grasped in several pair of forceps and the tumor pulled out into the wound. By means of several silk sutures, it was attached to the margins of the wound and the edges were trimmed off, making a large opening into the gall-bladder. The finger was passed down to the cystic duct, but on account of the necrotic condition of the sac it was considered inadvisable to make any attempt to sound the cystic duct.

During the following twenty-four hours the temperature fell to 99 and rose again at the end of the second day to 101, after which it gradually declined until the twenty-fifth day. Upon the eighth day the stone appeared at the mouth of the wound and was with some difficulty removed. It was half an inch in diameter and about an inch long, being pear-shaped and having a facet at one end, showing that another stone had been in contact with it. This was dislodged a few days later. The patient made an uninterrupted recovery, with one exception. On the tenth day after the operation the usual irrigation of the wall of the gall-bladder was undertaken by the nurse, but the mouth of the fistulous opening into the gall-bladder had now become so small that the irrigator point did not allow a free return of the water from the cyst, and as a result the water probably flowed through the cystic into the hepatic duct and carried back with it the pus from the gall-bladder. The patient complained of a sudden dreadful pain, quickly went into a collapse

from which he was with difficulty revived, and in the course of a few hours he had a pronounced chill and a rise of temperature to 103 degrees, as represented in the chart. This was unaccompanied, however, by any symptom of peritonitis, and upon the following day the temperature fell to normal and never rose after that time. This is shown by the accompanying chart. In the course of a few weeks the fistula completely closed, but it required a secondary operation to remove one of the silk sutures, which had been too hastily placed during the emergency of the first operation in an inaccessible position.

This case illustrates the fact that a stone may give rise to severe disturbance and nervous unrest and distress which can not be characterized as biliary colic, and may even initiate the morphin habit in an otherwise healthy and well-balanced man. It also shows the danger of irrigating the gall-bladder after the obstruction in the cystic duct has passed away. In this case the irrigations were begun on account of gangrene of a large part of gall-bladder, but I thoughtlessly neglected to give directions that the irrigations be stopped as soon as the stone was dislodged and the bile began to pour out.

Case 2.—Impaction of a stone in the cystic duct for five years, with attacks of pain and vomiting at intervals of two or three months, each lasting a day or two. Relief from all symptoms for five years. Impaction of the stone in the middle of the common duct; rupture of the common duct, removal of the stone, suture, drainage and death from shock. Mr. P. when I first saw him was 51 years old. He was suffering from an attack of "gastritis," the symptoms of which were pain at the pit of the stomach, general abdominal distress, persistent vomiting and considerable prostration. This attack came on the morning after Thanksgiving, presumably after an unusually full meal. He said he had had such attacks repeatedly for three years. Usually it had been necessary to give morphin to remove the severe, rather constant pain, which was always felt slightly to the right of the middle line of the abdomen and just under the edge of the ribs. The morphin was given hypodermically and the patient carefully examined. A small round tumor the size of a hen's egg could readily be felt almost touching the abdominal wall in the region of the gall-bladder. The liver was not enlarged, the stools were normal colored, there was no jaundice. A diagnosis of a stone in the cystic duct was made and an operation for its removal was recommended. The next day the pain had disappeared, the patient recovered during two or three days on a light diet, and an operation was refused. During the following three years this happened at irregular intervals two or three months apart, one of which always occurred on the morning following Thanksgiving. I attended him through each of these attacks and always recommended cholecystostomy. The patient submitted to a rather restricted diet and during the five following years he had no attacks of pain and often spoke of his wisdom in refusing an operation. At last, upon the morning after the eighth Thanksgiving he sent an imperative message to bring him morphin as he was suffering from another attack of gall-

stones. This time the pain was much more severe than ever before. The patient showed jaundice six hours after the beginning of the attack, which jaundice deepened gradually during the twelve hours following while we were waiting for the return of his wife in order to operate upon him. It was almost impossible to remove the exacerbations of pain, which came on first at 4 A.M., again at 7 A.M., again at 7 P.M. and lasted from this time continuously until he was operated upon the next morning at 11; but vomiting occurred only two or three times, and nausea was not a prominent symptom. At first a hypodermic of 0.03 gram of morphin was given. Six hours later a teaspoonful of chloroform in olive oil was given by the mouth. After this the pain was controlled by inhalations of chloroform at each paroxysm. His wife returned twenty-nine hours after the beginning of the pain. At that time his pulse was 100, temperature 98 in the rectum; his abdomen considerably distended and his skin in the second stage of jaundice. The abdomen was opened by a small incision in the median line high up, and immediately about a quart of greenish fluid poured out. The finger discovered a completely atrophied gall-bladder, and a stone an inch long and half an inch in diameter in the common duct about its middle portion. This stone had the appearance of two truncated cones set with their bases together. Its surface was dark and nodular. There was evidence of the former contact of a small stone at one end. A long incision was then made on the outer border of the right rectus muscle, the abdominal cavity was carefully washed out with a large quantity of sterile water. The liver and intestines were retracted with the assistants' fingers and a row of twelve fine silk sutures were placed in the wall of the common duct over the perforation, which was found directly over the stone in the middle and beginning lower third of the common duct. The stone was used as a guide in inserting the sutures. When the sutures had been placed a forceps was carefully insinuated into the opening and the end of the stone was grasped, and by the aid of the finger behind it and the forceps it was slowly and carefully withdrawn without much enlargement of the rupture. The duct was explored in both directions without result. The sutures were then drawn together and tied and cut off short. There seemed to be no leaking, and yet fearing this possibility, the omentum was brought up and fastened so as to make a deep well leading down from the long abdominal incision to the rupture in the common duct. This well was filled with strips of iodoform gauze in Mickulicz's handkerchief, and in order to make the drainage more complete a large perforated drainage tube was passed down the center of the gauze for a distance of five inches. Everything was held in place by a few sutures in the omentum, and the abdominal wall was closed, allowing about two inches space for drainage. The operation lasted an hour and a quarter. The patient seemed to suffer only moderate shock, the pulse and temperature at the end of the operation were only a trifle different from what they were at the beginning. During the eleven hours that the patient lived the symptoms of shock increased and the patient slowly but surely, and in spite of every means of stimulation and care, declined. There was no hemorrhage. The dressings were saturated with a greenish fluid; the urine was high colored and the perspiration yellowish. The patient died eleven hours after the operation without reaction. Superficial post-mortem examination through the wound revealed nothing new.

This case illustrates the danger of neglecting to open the gall-bladder and remove the calculus as soon as the diagnosis has been made. It is also a warning against neglecting to operate in case of obstruction of the common duct at as early a moment as possible. Although many cases of traumatic rupture of the gall-bladder have been reported in which recovery took place: after rupture, especially when due to obstruction by a gallstone and presumably accompanied by infection of the biliary apparatus, death from peritonitis is the rule. Mayo of Rochester, Minn., reports a case of injury of the gall-bladder in a boy 12 years old, with recovery after repeated removal of a biliary ascites, and many similar cases are reported. Peritonitis is produced not by bile but by infected bile.

Case 3.—Obstruction of the common duct, absence of the gall-bladder; disappearance of the calculus under manipulation; drainage of the peritonium; recovery. In August, 1894, Dr. Louis May called me to see a patient, 35 years old,

in whom he believed he had a case of obstruction of the common duct. The patient was a powerful, fat ice-man, of rather intemperate habits, who had suffered from frequent attacks of colic unaccompanied by jaundice. Three days before my observation he had been attacked with colic during his labor distributing ice. He administered to himself liberal doses of whisky, both hot and cold, and had one or two doses of morphia during the night hypodermically. The pain was very severe and the paroxysms were of rather long duration. In the morning he was completely jaundiced. The jaundice increased, the urine became black and the patient went into a comatose condition, with tympanites and occasional attacks of vomiting. This was the condition in which I found him. His jaundice was extreme; the clothing in which he lay was stained with bile. The urine removed from his bladder with a catheter was almost black. The respirations were shallow and the heart beats were faint. The pulse was 110 and the temperature 98. No tumor could be felt. The liver was considerably enlarged, extending downward about an inch and a half beyond the margin of the ribs. Operation for the removal of the obstruction was undertaken. The stools had been removed during the last two days by means of enemas and they were uncolored by bile. The patient was anesthetized with a small amount of chloroform and an incision made along the outer border of the right rectus muscle. The intestines were stained yellow, the liver itself looked almost black, so greatly was it engorged. The space in which the gall-bladder is usually found was occupied by a firm cicatricial mass, and the gall-bladder seemed to be entirely absent. Passing the finger down the common duct, at the first examination it seemed that a row of calculi could be felt, but a few minutes later and after a little further manipulation made to break up some light adhesions over the common duct, they entirely disappeared, nor could they, during the course of the operation, be felt again. At this time a greenish-yellow fluid was sponged out of the bottom of the abdomen and I was afraid, though I could not be certain, that I had ruptured the common duct. Pressure upon the liver caused distention of the common duct, and as soon as the finger was pressed upon it to milk it into the intestine the duct collapsed and the bile disappeared somewhere, presumably into the duodenum. I believed that the obstruction had in some manner been removed, and I feared that the common duct leaked into the peritoneal cavity. The stones could not again be felt; I did not think best to open the common duct and probe for them. Therefore, I built a sort of well leading down on the under surface of the liver between the right lobe and the quadrate lobe and paved the space with strips of iodoform gauze and sewed up the remainder of the wound, covering it all with an antiseptic dressing, held on with adhesive straps. The patient did not vomit after the anesthetic, and on the morning of the following day he was perfectly conscious, had a good appetite and several free bile-stained movements of the bowels. The wife made a superficial examination of the feces, but did not find any stones. This examination I consider valueless, however. The jaundice began to disappear. Upon the third day after the operation he resisted his wife's entreaties and the doctor's orders and dressed himself and went to his favorite saloons to see his friends. The doctor was called and induced a police officer to assist him in taking the patient home and putting him again to bed. The dressings were at first saturated with bile, but after a day or two the discharge was small, the packing was gradually removed and the wound closed without any event. The patient has not had an attack of biliary colic or jaundice since that time and has during the past four years been perfectly well.

This case illustrates the fact that after long continuance of calculi in the cystic duct the gall-bladder sometimes becomes atrophied, and it further illustrates the fact that the stones may be upon the verge of passing into the duodenum and need only slight assistance to dislodge them. It also shows that after forty-eight hours the adhesions about a Mikulicz's drain in the abdominal cavity are strong enough to withstand considerable assault. It seems to me now that in a similar case I should not be satisfied to leave a stone because I could not palpate it.

Case 4.—Repeated attacks of biliary colic for nine years, without jaundice; cholecystostomy and immediate removal of the calculus; recovery.—Mrs. P., 46 years old, the mother of five children, the youngest one 9 years old, had puerperal fever after the birth of this child. The symptoms were very grave. The patient had chills and fever and sweat for six or seven

weeks and recovered with broken health, very much emaciated. At the same time she had an abscess of one of her breasts, which required poulticing and afterward incision and drainage. When this child was 1½ years old she had an attack of colic, which lasted for three or four days, during which there was very severe vomiting and great prostration. From this attack she recovered promptly and since that time has had such attacks at frequent intervals, usually as often as two or three times a year. I was called to see her Feb. 13, 1896. She had been suffering for twenty-four hours with excruciating pain in the upper right side of her abdomen, extending into her back and right shoulder. A physician who had been treating her had made a diagnosis of gallstones and had attempted to administer remedies by the mouth, but on account of the frequent and persistent vomiting these remedies had had no effect. The pain was unabated and the vomiting occurred at intervals of ten to twenty minutes, with great retching. I found a large fat woman, with relaxed abdominal walls, moist skin, tender abdomen and a considerably contracted pupil, probably the effect of the morphia. There was no jaundice, and the liver was not recognizably enlarged. The urine was of normal color and contained only normal constituents. The temperature was between 100 and 101 degrees F. There had been no pronounced chill. The pulse was strong but rapid, 110. The patient looked anxious and begged for relief. I made a diagnosis of a single large stone in the cystic duct, and in trying to explain the condition to the husband I made a drawing of what I believed the stone to be, both in size and general appearance. This drawing he afterward compared with the stone which he saw removed. I administered a hypodermic of morphia, 0.03 gram, and urged an operation, basing my diagnosis wholly upon the symptoms. The abdomen was opened by a short incision in the median line and the finger pressed downward and to the right discovered the stone and a slightly distended gall bladder. A second incision was made along the border of the costal cartilage opposite the ninth rib, and the tumor was with some difficulty pressed up into the wound and fastened there with a couple of rows of strong silk sutures. The gall bladder was opened and the stone in the cystic duct was easily pressed forward into the gall bladder and outward through the wound. The stone corresponded almost exactly in size and shape with the sketch I had made of it before the operation. The wound was covered with antiseptic dressing, and during the following three weeks it continued to discharge more or less bile, when it closed suddenly and permanently. Since this time the patient has been wholly free from these attacks and has had no symptoms of sick headache.

This case shows the probable source of gallstones in the puerperal fever which the patient suffered a year and a half before any pain was felt. It also shows how long a patient is frequently neglected, suffering from stone in the cystic duct, a place so easily attacked and so amenable to simple surgical treatment.

Case 5.—Sudden impaction of stone in the cystic duct without previous symptoms of biliary colic or cholangitis, cholecystostomy and discharge of a large number of stones, with a single copious discharge of bile after ten days; closure of the fistula in two months, followed in the course of three weeks by renewed colic; second opening of the gall bladder; drainage for three months; recovery.—Mrs. E., aged 54, the mother of two healthy children, had never had any attacks of biliary colic or symptoms which could be referred to this condition. April 26, 1897, she was suddenly taken with a severe pain in the epigastrium, with vomiting and very slight indication of jaundice. The pain continued for twenty-four hours, with a chill at the end of this time and rise of temperature to 102. This was followed by repeated slight chills and a continuous high temperature for three days, when I was called to see the patient. She was a large woman of dusky skin and dark eyes. The abdomen at this time was excessively tender and in the region of the gall bladder especially sensitive, but by careful rolling of the tissues under the palm of the hand, a round smooth tumor could be felt, which was believed to be the distended gall bladder. There was nothing significant in the condition of the heart and lungs. The respirations and pulse corresponded with the temperature, which was now 102. The patient was much collapsed and begged to be relieved of the pain and vomiting. I recommended immediate operation, designed to relieve the gall bladder and remove the obstruction in the cystic duct.

An incision was made in the middle line large enough to admit the index finger, and the diagnosis of obstruction of the cystic duct and empyema of the gall bladder was confirmed. The gall bladder was surrounded on nearly all sides by light

adhesions, which did not, however, involve the anterior abdominal wall. An incision was made over the gall bladder and with some difficulty it was drawn up into the incision and fastened there by a row of silk sutures. The gall bladder was then opened and a cloudy whitish yellow fluid was discharged. The finger was passed into the gall bladder, but no stones could be found by a light examination. During the following ten days the patient rapidly improved, and a number of faceted gall stones were discharged. About this time the dressings were suddenly saturated for the first time with bile. A few more stones were then discharged into the dressings and the patient improved, but no more bile showed itself. July 1 the wound had completely closed, the patient was about and feeling well. July 26 the patient was again attacked with the same symptoms which she had suffered in April. I saw her at this time every day. On the third day I determined to reopen the gall bladder in the scar. The patient was as much prostrated as she had been before the first operation, and I determined now to keep the gall bladder open until I was certain that all stones were removed or dislodged. After this operation the gall bladder was drained until November 1, during all of which time there was a discharge of bile whenever the opening from the gall bladder was not plugged. After free drainage for two or three weeks without the removal of any stones, I introduced an olive-shaped urethral sound (about No. 15 American in size) into the gall bladder, and coiled up the silver handle to it so as to make a sort of spring resting against the abdominal wall, thus pulling the blunt side of the olive into the wound to act as a ball valve. This remained in the wound from the last of August until November 1, when it was removed. During all this time there was only a small and not very troublesome discharge of bile. The sound itself on removal was covered with the thinnest possible black film, which cracked, rolled up and fell off as soon as it had dried. I can not account for the obstruction which occurred in July. I was not able to find in the gall bladder, or in the cystic duct, or in the common duct any evidence of stone, although I was able without much difficulty to pass a sound into what I believed to be the intestine. During the past six months the patient has been very well and able to attend to her many duties.

Each of these cases has its own story to tell. In only one case did death result, and then because the warnings of biliary colic without jaundice were unheeded, and perhaps, too, because the necessities of the case almost demanded too great a delay after the last warning given by biliary colic with jaundice.

A CASE OF TUBERCULOSIS OF SPLEEN, WITH SURGICAL TREATMENT.

BY A. M. HAYDEN, M.D.
SURGEON TO ST. MARY'S HOSPITAL,
EVANSVILLE, IND.

A scarcity of literature on the subject of surgery of the spleen has induced me to report the following case, one that has been of unusual interest to me.

About Feb. 20, 1896, Mrs. Wm. F., age 24, first felt pain in the left hypochondriac region, which, slight at first, gradually grew more severe until she came under my observation, April 19, 1896. At that time the pain in the region of spleen was at times quite intense, while at others it was entirely absent. There was no rise of temperature, but her pulse was about 100. Her appetite was good, she had no cough or bowel trouble, and attended to her household duties as usual. I prescribed counter irritants externally and quinia and codein internally. Her condition remained about stationary until May 10, when her temperature was 101 degrees and pulse 120. The pain in the spleen was quite severe and on palpation I found quite an enlargement of that organ. She had no chills preceding the rise of temperature, nor other symptoms of malaria. She was well nourished, had rosy cheeks and weighed 108 pounds, which was her average weight.

Notwithstanding she had no symptoms of malaria, I put her on quinin, Fowler's solution and syrup of the

iodid of iron, with tincture of iodine externally, and kept her on a similar line of treatment for fifteen or twenty days, during which time her condition continued to grow steadily worse. I was still in doubt about my diagnosis and called council. After a thorough examination, which included the history of both her father's and mother's families, with negative results in regard to both tuberculosis and carcinoma, we were still in doubt about the nature of the trouble that was producing the tumor in the spleen, as it had now reached a size that would justify us in calling it a tumor. My council advised a trial of protonuclein, and it was given her for about two weeks. Meanwhile the tumor of the spleen continued to enlarge, forcing its way up under the short ribs and extending down into the left iliac region and over to the median line, reaching to the umbilicus.

An exploratory operation was done June 23, 1896. The incision was made over the most prominent part of the tumor. After reaching the peritoneal cavity we found the tumor free from adhesion to the abdominal walls.

It was softer than normal spleen structure and of a grayish color. I opened the splenic cyst or covering, which is composed of peritoneum and a fibrous coat intimately connected. Inside of the cyst we found a large mass of abnormal growth and broken down splenic tissue. After removing this soft tissue, which I did with my fingers and a spoon curette, I stitched the splenic cyst to the wall of the abdomen, leaving a cavity in the cyst as large as a baby's head, with no cystic wall separating it from the small portion of the splenic structure that was not removed.

I thoroughly packed the cavity with iodoform gauze and dressed the wound open to secure drainage, thinking that suppuration would take place and it would heal by granulations. A microscopic examination of the specimen removed blasted all such hopes, as it revealed pus corpuscles and tubercular bacilli.

The patient rallied well from the operation. Peritonitis developed on the second day, threatening to destroy the patient's life; after a few days she gradually improved.

Her pulse rate was unusually high compared with the temperature. A chart was kept for twenty-two days after the operation, from which I found an average morning pulse of 114.2, the highest rate being 150, which was noticed June 26, and the lowest 85, July 8. There was an average evening pulse of 119½. The highest reached was 144, June 27; the lowest, July 5, 98. During the twenty-two days there was a mean morning temperature of 99.5 degrees; the highest point being reached on the morning of June 26, 103 degrees; and the lowest July 8, 98 degrees. There was a mean evening temperature of 100.2 degrees; the highest on the evening of June 25, at which time it reached 104 degrees. The lowest evening temperature was 98.2 degrees, and occurred on the evening of July 14, 1896. The high pulse rate continued throughout the entire course of the disease. This high pulse rate has been a peculiarity of most cases of disease of both the spleen and pancreas that have come under my observation.

The patient gradually improved in her general condition as indicated by a good appetite, marked gain in flesh, weighing more three weeks prior to death than she had for several years previous. The opening into the spleen continued to discharge a small

quantity of pus. The tubercular growth in the splenic cyst gradually returned until it attained a size much larger than prior to the operation. She began to cough about six weeks before death; the cough became so persistent and severe that it interfered with sleep. The sputum contained traces of blood and tubercle bacilli. A physical examination revealed slight dulness over nearly the entire lung surface, but no marked flatness. Mucous râles were also present. The abnormal growth gradually crowded up into the opening in the abdominal wall until it rendered the operation of dressing very painful and interfered with drainage. In order to re-establish this and make the dressing of the wound less painful, October 14 I scooped out the entire contents of the splenic cyst through the original opening in the abdominal wall. The tubercular mass was very soft and easily broken up. The only instrument required in the operation was my fingers. After controlling the hemorrhage, which was quite profuse, I dried and packed the cavity with iodoform gauze. The patient rallied well from operation, and at the end of a week had recovered sufficiently to leave the hospital and return to her home. At this time her pulse rate varied from 140 to 150. A few days after returning home her condition grew worse and she gradually declined until November 4, when she died.

Autopsy, held November 5, revealed a great many foci of tubercular deposits in the liver. The pancreas was almost a solid mass of tubercular deposits. The splenic cyst was very much enlarged and partly filled with a cheesy substance which contained tubercle bacilli and pus corpuscles. The lungs were not examined.

Under the conditions was the operation justifiable? In my judgment, the operation was not only justifiable, but demanded. In all cases of tumors or other pathologic changes in the abdominal viscera that would in all probability be amenable to treatment by a surgical operation if correctly diagnosed, an exploratory incision should be made, and any other operation that might prove to be necessary should be done at the time of exploration. I am confident that her life was not only prolonged, but made more comfortable. After she recovered from the immediate effect of the operation, pain ceased; her appetite returned, and she gained considerable flesh; she became more cheerful; took an interest in her home surroundings, and was quite happy for a time, in fact, until the growth had returned and developed sufficiently to cause pain during the act of dressing.

Any other method of treatment would not have reduced the tumor, nor relieved the pain, and, therefore, could not have been as efficient. However, she received about the same internal treatment that she would have, had she not been operated upon, and consequently lost nothing from lack of non-operative measures.

I find that tuberculosis of the spleen is by no means of rare occurrence, but that it affects children more frequently than adults. The nodules may be small and gray, or large and yellow. In acute tuberculosis the spleen rapidly enlarges as the tubercles develop. Tuberculosis of the spleen is generally secondary to that of other organs of the body, while, in the case under consideration, the spleen seemed to be the first organ involved or the primary seat of the disease, the liver, lungs and pancreas becoming involved secondarily. Reynolds says, "tuberculosis is sometimes

located in the spleen, but almost, if not always, in connection with tuberculous growths in other organs, and generally in children." Rokitsky says, "in acute tuberculosis of spleen, the organ is smaller and softened very much like the condition it assumes in the typhoid state." Jenner says that it is often the seat of tubercle in children, but only in exceptional cases in the adult.

The lungs and mesenteric glands are very commonly diseased at the same time.

The tubercles are often distributed throughout the spleen substance with much regularity, and they may be solid and hard, but in the course of time they soften in the center, and assume a curdled appearance, or appear like cheesy substance. The "Reference Handbook" says, "acute splenic tumor, without tubercular deposits, occurs during the progress of acute tuberculosis." Splenic tubercles proper are apparently either always secondary to tuberculous growths in other organs, or appear simultaneously with widely disseminated tuberculous growths during the course of acute miliary tuberculosis. In the former case the tubercles are often not very numerous and are visible to the naked eye, varying in size from that of a millet seed to that of a pea, the largest doubtless being composed of several smaller aggregated tubercles. These growths are sometimes called solitary tubercles. They are at first grayish and translucent, assuming later a yellowish or cheesy appearance.

Tubercles of the spleen are alike devoid of interest for the clinician, the diagnostician and the therapist. Loomis says, "tubercles in the spleen develop in the spleen pulp." The nodules may be gray and small, or large, yellow and cheesy. Tubercular formations are very common in young children. Yellow tubercular masses, varying in size, are frequently formed in the spleen in connection with similar formations in other parts of the body; occasionally they soften and form abscesses. The small splenic vessels are often clogged with lymph and fibrin. Tubercles of the spleen can not be recognized during life.

Wm. Pepper says, "tubercle frequently attacks the spleen, but only as secondary to general tuberculosis."

Wilks and Moxon think the larger nodules of tubercle may be primary, but there seems to be no evidence in support of this opinion. As a symptom of general tuberculosis, splenic enlargement from congestion simply, and quite without any specific deposit, is observed as a form of acute splenic tumor. It is at the later stages of general tuberculosis that distinct deposits of tubercle are formed in the spleen, and these are consequently almost crude. It is usually impossible to diagnosticate the existence of splenic tubercle during life.

Dr. Orth says, "tubercular changes in the spleen are very common. Primary tuberculosis of the spleen must be very rare, if, indeed it ever occurs, but nowhere is secondary tuberculosis more common than in this organ."

At the time of the first operation the spleen was the only organ in the body that was affected. Would it have been good treatment to have removed it entirely? If so, what would have been the probable results had she survived the operation? If the organ had been removed, and as we believed at the time that was the only point of infection, the patient might have been permanently cured of the tuberculosis. The fact that the patient's health was very much improved after the operation and did not depreciate until other organs

became involved leads me to the above conclusions. Had complete splenectomy been performed, with the result of a complete cure of the tuberculosis, would her life have been prolonged sufficiently to have justified so formidable an operation?

Dr. Wyeth says, "complete splenectomy may be demanded in displacement of the organ followed by interference with the function of other viscera, or for the relief of pain caused by the spleen in an abnormal position." It has been performed in several instances on account of the enlargement of this organ in leucocythemia, but without the success which would encourage a repetition of the operation.

In Ashhurst, "International Encyclopedia of Surgery," Vol. V., p. 1103, I find the following statistics, causes for which the spleen has been excised: From a table published by Mr. Herbert Collier, out of twenty-nine operations performed for diseased conditions since the year 1549, thirteen have been for disease other than leucocythemia, and sixteen for leucocythemia of the gland. Of these sixteen all have been fatal. Of the diseases of the spleen unassociated with leucocythemia in which splenectomy has been performed, in two cases it has been a floating or wandering spleen; one, hypertrophy associated with a floating state of the organ; three, hypertrophy from malaria; three, simple hypertrophy; one, hydatid followed by sanious discharge; one, secondary enlargement after cirrhosis and associated with ascites and anasarca; one, sequestered spleen in peritoneal abscess; and in one hypertrophy, with a unilocular cyst containing three liters of a viscid fluid. Of these thirteen cases, eight have recovered. Of forty-three cases of splenectomy for disease, to which the editor has references, thirty-one are known to have terminated fatally, a proportion almost identical with that shown by Mr. Collier's figures. For injury of the abdomen, implicating the spleen and in several instances attended with protrusion, the results of excision and extirpation have been very encouraging. Nussbaum states that sixteen out of twenty-six operations performed for traumatic causes have been quite successful. (The editor has references to twenty-one cases of splenectomy for traumatic causes, all of which are said to have terminated successfully.)

Statistics are yet not sufficient to enable us to arrive at a satisfactory prognosis in such cases.

AN INTESTINAL OBSTRUCTION, DUE TO AN ABNORMALLY FORMED APPENDIX, ABNORMALLY LOCATED.

BY ANGUS McLEAN, M.D.

LECTURER AND DEMONSTRATOR OF ANATOMY, DETROIT COLLEGE OF MEDICINE; JUNIOR SURGEON, HARPER HOSPITAL, ETC.
DETROIT, MICH.

The patient who had this rare and unfortunate anatomic phenomenon was a man aged 40 and by occupation a foreman. He was taken with pain in the right lumbar and epigastric regions while at work; the pain was intermittent and gradually became more severe. He was compelled to quit work and go to his home. He became nauseated in a few hours and sent for his physician, Dr. Charles E. Bleakley. The Doctor examined the abdomen but found nothing of a localized character. He administered cathartics, and a slight anodyne for the pain, but the cathartics were ineffectual, and upon seeing him again he gave large doses of cathartics and had this followed by rectal

enemata, but this also proved ineffectual. The pain had now become so severe as to require occasional hypodermics of morphia. The Doctor grew suspicious of obstruction and had medical counsel called, but nothing definite was decided upon and the patient was continued upon symptomatic treatment.

I saw the patient on the fifth day and found the abdomen very much distended but no marked localized tenderness. He was not suffering from pain at this time, although he had had no anodyne for twenty-four hours, but appeared to be in a toxic condition. His temperature was 101 degrees F. and pulse 96. The attendant stated that this was the first day on which he had had any fever. I advised that a laparotomy be done at once, and the patient was removed to the Detroit Sanitarium and the operation performed.

After the anesthetic was administered and the tension of the abdominal muscles had relaxed, there appeared to be a slight fulness at the right side just above Poupart's ligament. An incision was made along the outer border of the rectus muscle (right side) opposite the umbilicus. The peritoneal cavity

C, cecum; A, ileum, surrounded by appendix and where obstruction took place; B, point of perforation; D, distended portion.

contained a slight amount of blood-stained fluid; the small intestine was distended and congested and of a dull red color, with some exudation and slight adhesions between its loops. The large intestine was normal in appearance. Upon manipulation a blind pouch of distended intestine appeared at the opening (resembling a Meckel's diverticulum). This was followed to its base and found to be attached to the lower portion of the cecum and to encircle the ileum at its junction with the large intestine, and in its swollen condition so encroached upon the ileum as to obstruct its lumen. The appendix was slightly gangrenous and perforated about one-half inch from the cecum in the portion extending from the cecum to the ileum. A small amount of fecal matter had escaped. The appendix was unwound from around the ileum and removed.

The accompanying diagram will show the position of this abnormal appendage, the heavy lines indicating the walls of the intestine and the dotted lines that of the appendix.

The specimen was seven and a half inches in length; the constricted portion, that is, the portion leaving the cecum and surrounding the ileum, was four and a half inches in length; the free portion three inches long and one and one-half inches in diameter and forcibly distended by gas. It was entirely devoid of mesentery and its canal was pervious throughout. The portion surrounding the ileum passed from behind forward and lay beneath the serous coat; *i. e.*, it was between the serous and muscular coats. The trouble evidently commenced in the appendix, and as the portion surrounding the small intestine became inflamed and swollen, it compressed the muscular coat of that portion of the intestine which it surrounded, gradually causing the obstruction.

Greves reports a case of intestinal obstruction due to the appendix, in the *London Lancet* of Dec. 6, 1884. In his case the free end of the appendix had become attached to the peritoneal wall, the body of the appendix forming an arch, under which a loop of the small intestine had passed and became strangulated.

Nicolaysen reported a case in the *British Medical Journal* of July 23, 1892. In this case the appendix had been previously inflamed and the mesentery of the appendix had become adherent to a portion of the small intestine; this afterward produced a volvulus.

I do not know of any similar case to the one I have described being reported by any writer, and this adds one more reason why the appendix should always be considered when the peristaltic action of the intestinal canal is interfered with.

NOTE.—The specimen was exhibited before the Detroit Medical and Library Association on Sept. 13, 1897.

STUDIES OF SOME FACIAL BONES.

Presented to the Section on Laryngology and Otology, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY MATTHEW H. CRYER, M.D.

PHILADELPHIA, PA.

The experience gained in a hospital devoted to the treatment of diseases of the jaws, face and associated parts, demonstrated to me several years ago that the text-book descriptions of the anatomy of these parts did not correspond closely with numerous observed clinical facts. To clear up the contradictory elements of this subject, I began, some four years ago, to make serial sections of such skulls as I could gain possession of, in all, numbering some hundreds.

These studies, some of which have been published, demonstrated that many of the printed, or text-book, description of the parts included, contained matter entirely at variance with observed facts.

Finding these printed errors so numerous in the anatomy relating to the parts embraced in the field of oral surgery, it was natural to carry the observations to more distant parts, and I found in them, as will be shown, that errors of description are far from uncommon in the works on anatomy relating to the nasal chamber.

When there is lack of bi-lateral symmetry of the part of the bony anatomy of the head, it is commonly associated with other marks of lack of bi-lateral symmetry, and vice versa; that is, if observation shows the dental arches, the palatal processes, and inferior maxillary bone to be bi-laterally symmetrical, bi-lateral symmetry usually exists in all of the bones, and so on.

Figure 1 shows an under view of a skull almost anatomically perfect, except that the external plates of the pterygoid process are not quite alike upon both sides, and there is a slight difference in the zygo-

Figure 1.

matic arches of the two sides. The skull is tilted slightly, so that the sides do not appear as symmetrical as they really are.

Figure 2.

Figure 2. Same skull gives a front view, the only lack of symmetry being a slight deviation of the septum of the nose. The bulla ethmoidalis of the left side is somewhat larger than that of the right, and the nasal septum is deflected from that side. It is often said that the septum is never straight. This, however, is an error, for I have many specimens in which it is perfectly vertical.

Figure 4.

Figure 3. The first of this series is a vertical section through the facial bones of a seven months fetus. The specimen is almost perfectly symmetrical, bilaterally. It shows the beginning of the development of the maxillary sinus, M. S. The line of junction between the superior maxillary and malar bones is

Figure 3.

well-marked, as is also the infra-orbital canal, lying beside the developing antrum. Attention is called to the appearance of this canal in section. It looks like a cross-section of a tube. Note the point of the nasal wall at which the invagination, which is to form the future sinus, begins; it is at a higher level than the

floor of the orbit. The direction of the developing sinus is downward and outward.

Figure 5.

Figure 4 represents the antero-lateral view of the skull, giving a general idea of the several external bones of one side of the face and head. The occlusion of the upper and lower teeth is almost normal. It shows the relations of the bones, of which we are to speak, to the other external bones. The outer surface of the lateral and anterior wall of the antrum is shown, the teeth having been denuded of the exter-
